uncertainties as well as because of the possible presence of bubbles, strain, and crystallites.

For natural rhyolite samples, roughly parallel trends exist in $k(T)$ for different amounts of crystals (Figure 8). Because scatter exists in the data, we approximate the effect of a small amount of crystals as $k_{\text{sample}} = k_{\text{remelt}}F$,

where k_{remelt} is taken from Table 3 and F is related to the crystal fraction X by $F = 1 + 0.071 X$.

4.4 An Additional Mechanism for Heat Transfer?

The decrease in thermal diffusivity of crystals near room temperature with increasing temperature has long been attributed to phonon scattering; the same response of D with T in glasses suggests that a similar mechanism operates. Above ~ 500 K, spurious increases in thermal diffusivity have been observed as a result of ballistic radiative transfer between the heater and thermocouple, which does not actually involve the sample. In LFA measurements, this unwanted ballistic radiative transfer has been removed at all temperatures, yet slight upturns in D are still observed for some types of silica [10] and for Fe- and Al-rich glasses and their melts (Figure 7). Data fitting suggests that positive linear coefficients exist for the other samples, although the slopes are poorly constrained [11]. These data show a correlation between the strength of the upturns and Fe^{2+} content and/or charge transfer between Fe^{2+} and Fe^{3+} for samples with low total Fe content. The picture at high total Fe is more complicated [16].

It is possible that some of the increase in D observed in glasses at high temperature may be due to the removal of defects by annealing. For melts, some of the increase could be due to flow of the sample within the experimental apparatus because very thin plates can sag under their own weight near the glass transition temperature [10].

Whether the increase in D with T could result from increased disorder with T is not yet clear. The heat capacity and D^{-1} depend similarly on temperature [10], so D drops, whereas C_p increases across the glass transition, both changes being a response to increasing disorder from glass to melt. Available data suggest that high-temperature heat capacities of most silicate liquids are constant or increase with temperature (Chapter 3.6). However, few thermal transport data are available on the same substances. Additional measurements at high temperature of both thermal diffusivity and heat capacity are needed for a complete understanding of the high-temperature increases.

One clue for the origins of the upturns is a positive correlation of the cT term in Eq. (14) with Fe^{2+} content, for low total Fe, suggesting a radiative process since electronic and vibronic transitions are linked [11]. However, in $(\text{Mg}, \text{Fe})\text{SiO}_3$ glasses, the effect is reduced for high Fe contents, whereas it is enhanced if Ca is present [17]. More measurements are thus needed to understand the origin of the diverse upturns in D at high T . Hofmeister [4] provides an explanation based on radiative diffusion

and the recent discovery that D of glasses and crystals depends strongly on sample length, if this is below ~ 1 mm.

5 Perspectives

The next decade will see measurements of technologically important materials such as metallic glasses (Chapter 7.10) and of glasses in the form of fibers (Chapter 9.3) and thin coatings (Chapter 6.8). Owing to the conflicting nature of available data, especially at high temperatures, however, an urgent need exists for improved accuracy and for benchmarking with identical glass samples to minimize complications possibly caused by internal strain and crystallites. Identical thickness must also be used, because vibrational overtones diffuse heat only for thick samples, whereas fundamentals participate at all thicknesses, and the proportions of the two mechanisms change with thickness for silica glass and crystalline solids as well [4]. The importance of thickness is implicit in Fourier's Eq. (4) but has been overlooked because of large experimental uncertainties in conventional, contact measurements. Contact-free techniques will be developed, or existing methods will be improved (e.g. to remove ballistic radiative effects from three-layer models). However, the current focus in method development is the study of thin films, for which only the fundamental vibrations diffuse heat. These methods have been benchmarked against data on thick samples and particularly metals, so the considerable uncertainties and the effect of ballistic transfer on insulators (e.g. oxide glasses) in the most modern techniques have gone unrecognized. We are particularly concerned with the accuracy of methods such as thermorefectance, which do not measure heat transfer over a well-defined distance, but instead involve extensive modeling of the signal. Fourier's equations require that the distance be known; otherwise the results involve tradeoffs.

Because heat capacity and density are central to determinations of D and k as well as to relating these transport properties, reliable data are needed on the thermodynamic properties as well, especially at high temperatures, for the materials of interest. Accurate thermal expansivity data on the materials of interest is needed to establish slight changes in thickness as temperature increases, which affect both k and D in any measurement. This is particularly important upon melting, where improvements in methods are most needed and are most relevant to glassmaking and understanding magmatic processes and environments. Accurate heat capacity data are needed because this is a weighting factor when multiple mechanisms, multiple carriers, or parallel heat flow configurations are involved [4].

Once accuracy is established, data from many laboratories can be used to establish firm correlations of k and D with chemical composition and related variables such as fragility and, most importantly, to determine precisely the dependence of D and k on temperature and length. Once these goals are met, improvements in theoretical models will certainly follow. A promising model is the radiative diffusion model of [4], which with one parameter provides a reasonable estimate for the complicated dependence of k on T from absolute zero to ~ 1000 K. Three parameters are needed for high temperatures due to the small size of H in Eq. (15). To test this model, spectroscopic data are needed on the same materials studied in transport experiments. For glasses, this involves cryogenic conditions for both infrared spectra and measurements of transport properties. For melts, higher temperature spectra are needed. This model is general and so addresses radiative transfer in magma chambers and large vats of glass, which involves diffusion of high-frequency light. This type of heat transfer cannot be measured in the laboratory, where conditions are optically thin in the near-IR and visible, and so testing the model at conditions where comparison with measurements is possible will ascertain whether the formulation of [4] is correct and can be applied with confidence to conditions unattainable in the laboratory.

Atomistic Simulations of Transport Properties

Junko Habasaki

School of Materials and Chemical Technology, Tokyo Institute of Technology, Yokohama, Kanagawa, Japan

1 Introduction

To begin with viscosity (Chapter 4.1) and ionic mobility (Chapters 4.2–4.4), transport properties are key parameters governing the kinetics of all processes involving glass-forming liquids, either industrially or naturally. Of course, much experimental and theoretical work has been devoted to these properties, but interpretations of the results are not necessarily unequivocal in terms of the basic mechanisms at play. In melts, the dynamics follow near the glass transition, a complex but universal frequency dependence whose origin has, for example, long been debated [1–3]. And it is probably superfluous to emphasize that viscosity is intimately connected to the fundamental problem of the glass transition (Chapter 3.2), which has not yet been solved in a general way.

As a complement to other kinds of approaches, atomistic simulations are useful to understand better transport properties of glasses and glass-forming liquids. Given the rather large number of atoms and long timescales to be considered to obtain insightful results, however, first-principles molecular dynamics (MD) calculations (Chapter 2.9) cannot be performed yet for this purpose, so this chapter will be restricted to classical MD simulations (Chapter 2.8). These are actually a useful technique to investigate the dynamics of atoms subjected to the classical laws of motion since the motion of atoms or ions can be tracked either individually or collectively to characterize it with the required detail as a function of time.

Owing to their fundamental importance, interatomic potentials used in MD simulations of transport properties will first be reviewed briefly. Relying mainly on the rest of the chapter on simulations made for lithium silicates, we will then introduce the concept of mean-squared

displacements (MSD) of ions as a function of time concerning reference positions. From the MSDs and related functions, one not only can distinguish time regions where the particles either move in cages, like in a crystal, or follow the diffusive regime typical of liquids but also can calculate transport properties such as the ionic conductivity or viscosity. How the coexistence of slow and fast ion motion gives rise to dynamical heterogeneities will then be discussed along the way to characterize them. Finally, insights on the mixed alkali effect will be presented and some features of the glass transition be discussed.

2 MD Simulations: Conditions and Potentials

Like MD methods, reverse Monte-Carlo simulations rely on the separability of the timescales of atomic and electronic motions to yield useful structural information (Chapter 2.8). They cannot produce directly particle trajectories, however, which is why classical MD with reliable interatomic potential is to be preferred for transport properties. In these simulations, practical constraints include not only system size and computing timescales (Chapter 2.8) but also the *strong* or *fragile* nature of the melts investigated, i.e. they depend on whether the dynamical properties are approximately Arrhenian or not (Chapter 4.1, [4]). The finite-size effects found for the former melts actually suggest that larger system sizes are required [5]. Besides, dynamical heterogeneities and the size of cooperatively moving regions of ions and atoms should be taken into account [3].

Of course, the adequacy of the selected interatomic potential to the problem investigated is of great importance. In addition, the choice of periodic boundary conditions must be checked since these can affect the

Reviewers: K.L. Ngai, CNR-IPCF, Largo Bruno Pontecorvo 3, Pisa, Italy
A. Takada, Research Center, AGC inc., Yokohama, Japan

cooperative motions of the mobile ions of the system as well as the network structure of the system. Particular attention must also be paid when slow dynamics are dealt with in glasses and supercooled liquids because the process can be considerably affected by rare events such as cooperative jumps of several ions. And another point to be mentioned is that the glass transition has usually been studied for binary melts because one-component systems were thought to crystallize readily. But this restriction is not necessarily serious if the system size is not too small [6], whereas these systems have in fact the important advantage of allowing rigorous theoretical treatments to be performed thanks to the validity of exact dynamic scaling laws.

For transport properties, the purpose of a simulation is not necessarily to reproduce faithfully the real system but, rather, to pinpoint the key structural or dynamical features at work. Likewise, the functional form of the potential and the precise values of its parameters are not critical for a most general phenomenon such as the glass transition. This is why relatively simple potentials such as soft-core (SC) or Lennard-Jones (LJ) potentials have been extensively used. The former is gaining importance because it is considered as a basis for understanding thermodynamic scaling. It consists of a repulsive, power-law term of the form

$$\varphi_{ij} = \varepsilon \left(\frac{\sigma}{r_{ij}} \right)^n, \quad (1)$$

where r_{ij} is the distance between particles i and j , whereas ε and σ determine the depth and size of the potential well, respectively. The hard-sphere model is the limiting case of Eq. (1) when n approaches infinity. As for the Lennard-Jones potential, its most general form is

$$\varphi(r) = \frac{E_0}{(q-p)} \left[p \left(\frac{r_0}{r} \right)^q - q \left(\frac{r_0}{r} \right)^p \right], \quad (2)$$

where E_0 is the depth of the potential well, r_0 the position of its minimum, and the parameters p and q have been given various values. The Lennard-Jones values with $p = 6$ and $q = 12$ have been extensively utilized in models of the glass transition (e.g. [7]). Variants of this model with the other values $p = 11$, $q = 12$ and $p = 5$, $q = 8$ have been selected to investigate the effect of the potential functions on the glass transition simulated for systems of different fragilities [8].

In dealing with specific properties of silicate and other ionic melts, however, recourse must be made to more realistic potentials. A Gilbert–Ida-type repulsive potential combined with Coulombic force has, for instance, been used successfully for silica and silicates [3]:

$$\phi(r_{ij}) = \frac{q_i q_j}{r_{ij}} + f_0 (b_i + b_j) \exp \left(\frac{a_i + a_j - r_{ij}}{b_i + b_j} \right) - c_i c_j r_{ij}^{-6}, \quad (3)$$

where the first term on the right-hand side represents Coulombic interactions and r_{ij} designates interatomic distances (Å), a_i the ionic radius of atom i and b_i its softness parameter (also in Å), and f_0 a constant parameter ($=1$ kcal/mol/Å). As for the $c_i c_j$ parameters (kcal Å⁶/mol), they are introduced for correcting the curvature of pair interactions involving oxygen atoms. This potential has the advantage that each of its terms is additive not only for pair but also for atomic species, so it allows complex systems such as mixed alkali melts and glasses to be treated.

In this chapter, the potential used for lithium silicates is of the type (3) with parameters derived from *ab initio* MO calculations [9]. As a severe control of the quality of these parameters, the potential has been checked against the stability of lithium disilicate and metasilicate polymorphs at constant pressure. Even though it is not fully realistic, its quality is good enough for discussing dynamical mechanisms.

In ionic liquids, the inner structure of the ions must in addition be accounted for. An adequate potential often used for representing both the interaction among ions and interactions within each ion is of the form [3]

$$\begin{aligned} \varphi(R) = & \sum_{\text{bonds}} K_r (r - r_{\text{eq}})^2 + \sum_{\text{angles}} K_\theta (\theta - \theta_{\text{eq}})^2 \\ & + \sum_{\text{dihedrals}} \frac{V_n}{2} (1 + \cos [n\varphi - \gamma]) \\ & + \sum_{i < j}^{\text{atoms}} \left(\frac{A_{ij}}{R_{ij}^{12}} - \frac{B_{ij}}{R_{ij}^6} \right) + \sum_{i < j}^{\text{atoms}} \left(\frac{q_i q_j}{\epsilon R_{ij}} \right). \end{aligned} \quad (4)$$

In Eq. (4) the first three terms describe bond, angle, and dihedral deformation energies, whereas the fourth represents a standard pairwise (6,12) Lennard-Jones potential and the last characterizes Coulombic interactions between atoms with charges q_i and q_j .

3 Dynamics

3.1 Mean-squared Displacements and Diffusion Coefficients

As a starting point in dynamical studies, one calculates the MSD of the positions of an ensemble of particles over time with respect to a set of reference positions. Whereas the MSD is restricted to the vibrational amplitudes in solids, in liquids, it increases continuously with time as a result of diffusive motion so that the transition from solid- to liquid-like displacements can be clearly distinguished. From the successive positions occupied by the particles considered, the MSDs are readily calculated with

$$\langle r^2(t) \rangle = \left\langle \left\{ \sum_{i=1}^N (r_i(t) - r_i(0))^2 \right\} / N \right\rangle, \quad (5)$$

where r is the displacement of particle i , be it an ion, an atom, or a molecule, N is the number of the species. As for the angled brackets, they represent in Eq. (5) an ensemble average for an equilibrium system or average for a long time for a glass or a quasi-equilibrated system exhibiting slow dynamics. In general, fast and slow motions of ions or atoms coexist with jumping or hopping between sites. To average out the resulting dynamical fluctuation is not necessarily easy when performing runs with different initial configurations because of the extremely large number of runs then required. Instead, it is better to average many time-series taken from a long run or some long runs along with time windows covering a wide range of initial times [3].

As a first example, the MSD of Li^+ in lithium metasilicate at 700 K, i.e. near the glass transition, can be divided into four regimes delineated by characteristic times (Figure 1a). Because $\langle r^2 \rangle \propto t^2$ at the shortest times, the motion is simply ballistic before the onset of a combination of vibrational and relaxation contributions is

observed. The vibrational contribution to the MSD becomes constant after ~ 1 ps. The MSD is nearly flat in this first interval, which owes its name of nearly constant loss (NCL) region to the near constancy of the dielectric loss. In time region II, some jumps to nearby sites are observed, so the MSD becomes nearly proportional to time. In the power-law region (III), the MSD is modified by the angle formed by the directions of two successive jumps before the diffusive region (IV) is finally attained at the time t_{dif} after which the MSD determines the elemental timescale of diffusion coefficients.

Diffusion coefficients are indeed the related important properties readily calculated. For a particle i , this coefficient is derived with the following Einstein equation from the MSD:

$$D = \frac{1}{6} \lim_{t \rightarrow \infty} \frac{d}{dt} \langle [r_i(t) - r_i(0)]^2 \rangle. \quad (6)$$

Given the finite timescales of MD runs, the calculation must of course be performed in the actual diffusive time region after t_{dif} .

Analogous time regions are found in MD simulations of 1-ethyl-3-methylimidazolium nitrate (EMIM- NO_3), an ionic liquid (Figure 1b) [3]. In this case, the relatively steep slope in the NCL region means that motions at short times have larger amplitudes, which is why the system can remain in the liquid state at much lower temperatures than for silicate systems.

Since atomic mobility of course decreases with decreasing temperatures (or with increasing pressure), the widths of the four time regions then become accordingly greater. At low temperature or under high pressure, region II may thus be erroneously regarded as a diffusive region, and the true diffusive region IV is no longer observed if it requires observation times longer than the timescale of the MD simulation. Conversely, long simulation times are required for studying slow dynamics.

Usually, the diffusion coefficients of ions depend on the rate at which the system that has been vitrified. Interestingly, the diffusion coefficients of Li^+ in rapidly quenched lithium silicate glasses are comparable with the experimental values [3, 10, 11] although experimental systems are usually more slowly cooled. This result thus suggests that, with respect to actual atomic rearrangements in macroscopic systems, the bias due to high cooling rates in MD simulations is compensated by other bias resulting from the small size of a simulated system subjected to periodic boundary conditions.

Figure 1 Time regions of mean-squared displacements as derived from MD simulations and delineated by the characteristic times t_{x1} , t_{x2} , and t_{dif} . Dotted line, power law in the NCL region; short dashed line, power law in region III. In Region II, MSD is nearly proportional to time. Solid line: linear dependence in region IV. (a) For Li^+ in lithium metasilicate glass at 700 K. (b) For EMIM^+ ion in the ionic liquid (EMIM- NO_3) at 400 K.

3.2 Temporal and Spatial Aspects of the Dynamics

In region III, the MSD of Li^+ ions in lithium silicates shows a power-law dependence when plotted against the cumulated number of jumps, whereas the cumulated

numbers of jumps follow a linear trend when plotted against time. Hence, the power law in region III originates in geometrical correlations between successive jumps. In a log–log plot, the change in the slope of MSD with decreasing temperatures then is caused by the complexity of the trajectories whose correlated back motions considerably contribute to the dynamical slowing down. The distribution of waiting times before jumps is generally another useful source of information on stochastic processes. For particle jumps, this waiting-time distribution shows a power-law tail at timescales comparable with the timescale of region III, so one might consider that it is at the origin of the power-law dependence of the MSD. This apparent discrepancy in the explanation of origins of the power law is caused by differences in the observation methods of the renewal jump processes. The reason is that the jumps of an ion to the next site and back to its original site are both counted in the analysis made for separating the temporal and spatial terms, whereas the returning ion is not counted in the calculation of the waiting-time distribution. Obviously, the time dependence of the MSD refers to the former situation. Thus the waiting-time distribution is not at the origin of the power-law time dependence of the MSD of ions. But the change in the waiting-time distribution nonetheless contributes to the slowing down of the dynamics through its effect on the mean jump rate at low temperatures.

3.3 Transport Properties

For a single-ion system, the ionic conductivity is related to the MSD of the ions by [12, 13]

$$\sigma^*(\omega) = -\omega^2 \frac{Nq^2}{6H_R kT} \int_0^\infty \langle r^2(t) \rangle e^{-i\omega t} dt, \quad (7)$$

where N is the number density of mobile ions, q the ion charge, k Boltzmann constant, T temperature, and H_R the Haven ratio (Chapter 4.2) between the tracer and bulk diffusivities, $H_R = D_t/D_b$. The D_t term in Eq. (7) is related to the geometrical correlations existing between two successive jumps of the ions from one site to another affected by other atoms and ions, whereas the D_b term is related to the collective property of all ions. Hence, the deviation of this ratio from unity is a measure of the cooperativity of their motions. The time dependence of H_R can also be evaluated [12] with

$$H_R(t) = \frac{\sum_i \langle \mathbf{v}_i(0) \cdot \mathbf{v}_i(t) \rangle}{\left\langle \sum_i \mathbf{v}_i(0) \cdot \sum_j \mathbf{v}_j(t) \right\rangle}, \quad (8)$$

where $\mathbf{v}$ is a velocity vector.

In equilibrium MD simulations the viscosity, η , can be directly calculated from the Green–Kubo relation [12, 14], which expresses transport properties in terms of the integrals of the autocorrelation functions of the off-diagonal components of the stress tensors. If needed, however, the viscosity can also be determined in nonequilibrium MD and reverse MD simulations. More simply, it is often derived from the diffusivity of atoms through the Stokes–Einstein relation (Chapter 4.3). Near the glass transition, however, deviations from this relation are often found, so a fractional power law can then provide a better description of dynamics over wide temperature ranges [1].

3.4 Space-time Correlations

The next step is to characterize the spatial and temporal distributions of pairs of particles in the system investigated. It is accomplished in terms of the van Hove function [15, 16], $G(\mathbf{r}, t)$, which expresses the probability of finding a particle j at a given positional vector $\mathbf{r}$ at a given time t , when the particle i was initially located at a reference point:

$$G(\mathbf{r}, t) = \frac{1}{N} \left\langle \sum_{i=1}^N \sum_{j=1}^N \delta[\mathbf{r} + \mathbf{r}_i(0) - \mathbf{r}_j(t)] \right\rangle, \quad (9)$$

Characterizing the structure and dynamics of the system, the van Hove function is a Fourier transform of a dynamic structure factor $S(\mathbf{k}, \omega)$ that depends on a wave number vector and a frequency variable. It can be split into self-part and distinct parts, the former and latter accounting for the cases $i = j$ and $i \neq j$, respectively. The self-part describes the motion of the initially marked particle at t for an observer whose eye is fixed on the initial position. It is defined as

$$G_s(\mathbf{r}, t) = (1/N) \sum_{i=1}^N \langle \delta(\mathbf{r}_i(t) - \mathbf{r}_i(0) - \mathbf{r}) \rangle, \quad (10)$$

where $\mathbf{r}$ designates a positional vector. In Figure 2, it has been calculated for various timescales for Li^+ ions at 700 K in lithium metasilicate for $r (=|\mathbf{r}|)$ and multiplied by $4\pi r^2$ so that the areas under the curves are proportional to the numbers of particles. If the function $G_s(r, t)$ obeys the Gaussian form, the solution of the diffusion equation will be [16, 17]

$$G_s(\mathbf{r}, t) = \frac{1}{(4\pi Dt)^{3/2}} \exp(-\mathbf{r}^2/4Dt). \quad (11)$$

For comparison, Gaussian functions yielding the same diffusion coefficient as the van Hove function are also shown. They are represented [3] by stable distributions with inverse exponential tails, $f(X) \sim |X|^{-1-\alpha}$, and

Figure 2 Self-part of the van Hove function of Li^+ ions in lithium metasilicate at 700 K: comparison of the MD simulated values for the indicated timescales with Gaussian dynamics (smooth curves) using Eq. (11), yielding the same diffusion coefficients. Both localized and delocalized ions exist.

exponential truncations. The exponent α is a Lévy index, $0 < \alpha < 2$ [18], which characterizes the form of the probability distribution the functional form being Gaussian when the value of α is 2. Clearly, one observes in Figure 2 heterogeneous (i.e. non-Gaussian) dynamics characterized by tails that extend farther when the time-scale increases. The deviation of the functional form from Gaussian implies the coexistence of fast and slow ions, which will be characterized later.

To understand mutual ionic motions, the distinct part of the van Hove function is calculated from

$$G_d^{\alpha,\beta}(\mathbf{r}, t) = (1/N_\alpha) \sum_{i=1}^{N_\alpha} \sum_{j=1}^{N_\beta} \left\langle \delta(\mathbf{r} - \mathbf{r}_i^\alpha(0) + \mathbf{r}_j^\beta(t)) \right\rangle, \quad (12)$$

where N_α and N_β are the numbers of ions α and β , respectively, and the self-term $i = j$ is left out in the summations if $\alpha = \beta$.

If an ion β comes onto the site previously occupied by an ion α at the initial time t_0 , a new peak develops at around $r = 0$. Once normalized by the density, the function at $t = 0$ corresponds to the pair correlation function, $g(r)$.

The intermediate scattering function, which is a Fourier transform of the self-part of the van Hove function, can then be calculated with

$$F_s(k, t) = \left\langle \sum_{j=1}^N \exp \{ i\mathbf{k} \cdot (\mathbf{r}_j(t) - \mathbf{r}_j(0)) \} \right\rangle / N \quad (13)$$

where the $\mathbf{k}$ is the wave number vector difference before and after scattering. This function can be obtained from inelastic neutron scattering measurements (or related

Figure 3 Intermediate scattering functions of Li^+ ions for the eight wave numbers indicated ($\text{\AA}^{-1}$) as a function of the MD simulation timescale in lithium metasilicate at 800 K.

ones). For Li^+ ions in lithium metasilicate at 800 K, it is a strong function of the wave number (Figure 3). It decays in several stages, which correspond to the time developments of MSD and van Hove functions. At the greatest wave numbers, the function accounts for short length-scale motion. It decays faster in the short time region, whereas at smaller wavenumbers (long length-scale motion) it shows a slower decay with a Kohlrausch stretched exponential form (Chapter 3.7),

$$\phi(t) = \exp \left[- (t/\tau)^\beta \right]. \quad (14)$$

The observed heterogeneous dynamics thus results from a combination of motions characterized by different length and timescales. A similar situation is found in other systems. In supercooled liquids, a fast β -process is observed at an early stage of the function, and it is then followed by slow α -relaxation [1].

4 Insights into Dynamic Heterogeneities

4.1 Slow and Fast Ion Motion

As exemplified in Figure 2, dynamics not described by Gaussian functions nor Brownian motion have been observed in many systems. Atoms or molecules in supercooled liquids, ions in ionically conducting glasses, and ionic liquids generally show such a dynamic *heterogeneity*, which actually originates from the coexistence of fast and slow atoms or ions. This frequent occurrence thus suggests the existence of underlying fundamental features common to these systems. Before looking for them, however, one needs a more precise definition of *fast* and *slow*. The definition can, in fact, be given in two complementary ways. In the first definition, one designates by *fast*

a dynamics accelerated by the forward correlated motions (or long jumps) and by *slow* dynamics retarded by ions with a localized motion and of a long waiting time between jumps. The second definition refers instead to decay rates, which are *fast* in short-time regions and *slow* in long-time regions involving diffusive motion with both accelerated and localized motions. In the following, we will use the first definition.

4.2 Characterization of Dynamical Heterogeneities

Jumps in supercooled liquids are readily visualized by MD simulations to give a detailed picture of ionic motion in terms of density maps where ion sites are defined by those positions that accumulate during the run. In a 2 ns ($\sim t_{\text{diff}}$) MD simulation of lithium disilicate at 500 K (Figure 4), one clearly distinguishes in this way isolated sites from extended channels through which diffusive motion of Li^+ ions takes place within the network of SiO_4 tetrahedra. In more detail, the displacements calculated in 1 ns

Figure 4 Atomic positions visited in a 6-Å slice of Li_2SiO_3 glass during a 2 ns run at 500 K. (a) Dark dots, Si and Li; light dots, O. (b) The same plot for Li^+ ions only, which contrasts sites either isolated or defining diffusion channels.

Figure 5 Absolute values of displacements at 500 K of five arbitrary chosen Li^+ ions. Initial values shifted upward to avoid overlaps.

for five arbitrarily selected ions clearly illustrate their dynamical heterogeneity (Figure 5). Two of these ions kept localized during the whole period. Two others underwent intermittent spike-like motion with an amplitude typically lower than 1.7 Å and a high back-correlation probability caused by site caging, which represented prejump motions found in the NCL region. Jumps were observed beyond a neighboring site for only one ion (Figure 5, top), which contributed to diffusive motion. Unsurprisingly, the longer and/or successive jumps contributing to diffusive motion are found more frequently at higher temperatures.

It is the decoupling between the timescales of the slow motion of network formers and the fast motion of mobile ions that results in the existence of recognizable ion channels in ionically conducting materials such as silicates. The structure of these ion channels (or jump paths) has long drawn the attention of researchers. Its importance in ionics has been well documented [3, 19, 20], so it is widely accepted. As an example, the fast motion of Li^+ ions in borate glasses has been related to the distribution of nonbridging oxygens [19] as expected from the built-in association of these oxygens with network-modifying cations.

4.3 Multifractal Analyses

As a matter of fact, large displacements tend to occur through cooperative jumps of several ions after time intervals that become shorter when the temperature increases. The very strong effects of temperature are clearly revealed by the marked contrast between the contour plots of Li^+ density maps calculated at 700 K and 1673 K for lithium metasilicate (Figure 6). The ion sites and paths are well recognized at 700 K: the dense zones represent long residence times on site involved in localized jumps, whereas the rarefied ones represent channels delineated by diffusive jump motion among shallow ion sites. At 1673 K, the distinction between these two kinds

Figure 6 Spread of diffusive motion with increasing temperature in lithium metasilicate: a contrast between the contour plots of the density maps of Li^+ ions for 1 ns ($\sim 2 t_{\text{dif}}$) at 700 K (top) and for 400 ps ($\gg t_{\text{dif}}$) at 1673 K (bottom) as seen in an MD basic cell. Grids used for counting were 1/2 (for the length) of those shown in the figure. Program VENUS [21] was used for visualization.

of sites has nearly vanished as a result of a general spread of diffusive motion that leaves only a few remaining islands with relatively long residence time.

Such patterns of sites and paths are too complex to be characterized by a single fractal dimension, but they lend themselves to a multifractal analysis made in terms of singularity $[f(\alpha)]$ spectra [22] where the exponent $f(\alpha)$ represents the dimension of the part of the density profile that has a singularity of strength α . These spectra thus represent the distribution of structural dimensionalities and are, as such, useful measures of heterogeneities [22–24]. For Li^+ motion, temperature has an obvious effect on these spectra (Figure 7). Whereas their convex shape points to a multifractal character (mixing of exponents), their width decreases markedly with increasing temperatures as a result of increasing mixing of localized and diffusive motions of ions and, thus, of decreasing heterogeneities. Correlatively, the higher α -values at the highest temperatures indicate a larger spatial spreading and largest $f(\alpha)$ at the maximum means the largest capacity dimension (~ 3), which in this case is consistent with percolation of the ion channels during the timescale of the simulation.

Figure 7 Singularity (multifractal) spectrum, $f(\alpha)$ for Li ions obtained from the density profile of Li ions during 1 ns at each temperature.

4.4 Non-Gaussian Dynamics

By definition, heterogeneities may be neglected if one is interested only in the mean dynamics of the system or if a *coarse-grained* MD simulation is performed whereby the system structure is simplified through a selection of its most salient aspects so as to reduce considerably the computing effort. In contrast, heterogeneities need to be considered to understand non-Gaussian dynamics at certain timescales, the non-Arrhenian temperature dependence of transport properties, or other nonlinear features such as the mixed alkali effect. Even in the former case, one should note that the mean value itself is affected by the heterogeneity of the dynamics.

Deviations from Gaussian dynamics are characterized by the following non-Gaussian parameter [16]:

$$\alpha_2(t) = (3/5) \langle r^4(t) \rangle / \langle r^2(t) \rangle^2 - 1. \quad (15)$$

which thus vanishes if the system obeys a Gaussian form. When evaluated at several temperatures for Li^+ ions [3], $\alpha_2(t)$ begins to be very small at short times, increases up to a maximum at around t_{x_2} , and then decreases slowly. In other words, α_2 increases until Li^+ ions jump out of their cages, and then it decreases as a result of the contribution of successive jumps with a large back-correlation probability.

The maximum value of α_2 , therefore, does not necessarily represent the largest heterogeneity. Hence, one may need to use other measures of heterogeneity such as the Lévy index, two cumulants [25], the variance, and the kurtosis of the distribution of the self-part of the van Hove function and multifractal spectra. From a physical point of view, convergence to a Gaussian form is expected through the exchange of slow and fast dynamics at longer timescales [26]. Consistent with this idea, Sokolov and his coworkers [27] have shown that the (power law) truncated Lévy flights slowly converge to a Gaussian form. For arbitrarily truncated Lévy flights, Vinogradov [25] has pointed out that the high-order cumulants vanish when the number of steps tends to be infinite so that the dynamics become Gaussian as well.

Before following Gaussian regimes, however, ions (or atoms, molecules) would spread considerably (Figure 2) to form multifractal structures (Figure 6) that differs from those of the Gaussian Dynamics [3].

5 Mixed Alkali Effect

The mixed alkali effect is characterized by strongly non-linear variations of transport properties when an alkali substitutes for another, for instance, by a minimum in viscosity [3] or by a maximum in electrical resistivity, whose origin has been extensively debated [28–36]. In MD simulations [30–32], an interesting inference drawn from the distinct part of van Hove functions has thus been the lack or decrease of jump motion between the different alkali-ion sites in mixed alkali glasses. The question has then been to determine how this existence of nearly distinct jump paths can account for the mixed alkali effect observed macroscopically.

For this purpose, consider the diffusivities of Li^+ and K^+ in mixed $(\text{Li}_{1-x}\text{K}_x)_2\text{SiO}_3$ at 700, 800, and 1673 K, which exhibit minimum values near the $x = 0.5$ in both glass and liquid states (Figure 8a). Interestingly, similar variations are calculated for the fractal dimensions of the random walks since the $2/d_w$ values of Li^+ ions decrease upon mixing with K^+ ions (Figure 8b) and vice versa. In addition, a change in the power-law exponent of the MSD is observed. Denoting by d_{w1} and d_{w2} the fractal dimensions of the random walk of the shorter (≤ 3 Å) and longer length scale (> 3 Å), respectively, one observes that the difference between d_{w1} and d_{w2} becomes smaller upon (Li, K) mixing, so it is related to the suppression of collective motions in the mixed systems. Finally, changes in paths upon mixing have also been found in density profiles [32] whose $f(\alpha)$ spectra indicate that the capacity dimension for the Li^+ path decreases upon mixing with K^+ (Figure 9). It has thus been concluded that the slowing down of the dynamics originates from the increase of the back-correlation probability of the motion within channels. This probability is itself related to the fractal dimensions of both random walks, d_w , and pathway, d_t [3, 31, 32]. The d_w value is a measure of the complexity of the trajectory that has a value of 2 when the motion is a free random walk.

A similar disruption of jump paths in the mixed $\text{Li}_x\text{Rb}_{1-x}\text{PO}_3$ has also been described from reverse Monte-Carlo simulations of structures made with the bond-valence technique [33]. Either from MD or Monte-Carlo simulations, there is a consensus on the role of the dimensionality of paths in the mixed alkali effect although some details depend on the assumptions used in each analysis.

There has in fact been a close relationship between experiments, theory, and simulation on this problem

Figure 8 Mixed alkali effect for alkali diffusion in $(\text{Li}_{1-x}\text{K}_x)_2\text{SiO}_3$. (a) From top to bottom, diffusivities at 1673, 800, and 700 K as a function of x ; solid symbols, Li^+ ; open symbols, K^+ . (b) Changes in the reciprocal of the fractal dimension of the random walk, $2/d_w$, and in the power-law exponent of the MSD, θ at 700 K.

Figure 9 Mixed alkali effect for alkali diffusion in $(\text{Li}_{1-x}\text{K}_x)_2\text{SiO}_3$. Singularity spectrum of Li^+ ions obtained from 1 ns runs at 700 K for $x = 0$ (rectangles), 0.25 (triangles), and 0.5 (diamonds). Systematic decrease of the capacity dimension for the channel of Li^+ ions found with increasing of K^+ content.

[3, 28–36]. For example, Jain and Lu [36] have pointed out that the mixed alkali effect is not found in AC conductance at low temperatures, which is consistent with the results of MD simulations. Besides, the mechanism of confinement by fixed or pinned particles or walls

[3, 37] bears a definite similarity with the mixed alkali effect. When a randomly chosen small number of ions (or particles) are pinned down, the mobility of the majority of ions decreases concerning path changes. When ions in the wall of the basic MD cell are fixed, the intermediate scattering function indicates that the dynamics of the other ions gradually changes at a distance from the wall because the decay is slower and more stretched near it. In this case, the paths change only slightly for the majority of mobile particles, which means that the effect of the blockage propagates over a longer distance [1, 32].

6 Glass Transition and Thermodynamic Scaling

In addition to the glass transition temperature T_g , another characteristic temperature T_B has been identified in fragile liquids as a kink in the temperature dependence of relaxation times [3]. Recent MD work for ionic liquids has contributed to the understanding of this feature through the prediction of changes at the same T_B in the slopes of ion diffusivities, which can be observed in log–log plots. The simulated volume and partial potential energies for terms such as Coulombic, bonds, and angles of the system show inflections at both T_B and T_g , which correlate with changes in the geometrical freedom of the system. That is, a saturation of the number of fictive bonds (contact ion pairs) occurs near T_g , so the geometrical degree of freedom of the coordination polyhedra varies at T_B , in agreement with experimentally observed changes in the free volume of the system.

Complex variations of relaxation or transport coefficients in supercooled liquids, ionics in the glasses, and their dynamics are rather general and obey a thermodynamic scaling [3]. The validity of the scaling has been confirmed by MD simulations for some systems that include ionic liquids. Dynamical properties such as diffusion coefficients, D (or D/T), viscosity η , the timescale of α relaxation, τ_ω and some other physical properties are a function of the product ρ^γ/T , where ρ is the density of the system and T the temperature, i.e. the dynamics of many materials can be represented by a master curve characterized by the exponent γ of the density.

7 Perspectives

For MD simulations of slow dynamics near or below the glass transition temperature or of bigger or more complex systems including functional ones such as solid-state batteries (Chapter 9.5), the calculation speed may be expected to keep increasing as a result of further progress

in computation technology. Besides, coarse-grained modeling will be useful for systems possessing inner structures such as ionic liquids.

Different kinds of simulations will also be developed. Hyperdynamics with modified potential functions and/or temperature have, for instance, been introduced to search for free energy surfaces or rare events [38]. They seem to be useful, but some questions need to be clarified before applying them to supercooled liquids and glasses. How do modifications of the potential function affect the structure of the system and its long-time dynamics? Will they change the exponent connecting short- and long-time dynamics or not? If the applicability of such methods is established, then calculation costs will diminish considerably. With these developments, however, quantitative estimations of numerical errors for long runs and/or for hyperdynamics will remain necessary.

Thermodynamic and related entropy scaling should be tested for more systems, with respect to every species, to understand the general physics behind them. Using the thermodynamic scaling and/or related rules, one could then extend predictions of dynamics in a wider range of temperatures and pressures.

Finally, *ab initio* MD methods are promising approaches (Chapter 2.9) even though they are currently limited to small system sizes and short timescales because of calculation times 10^3 – 10^5 times longer than with classical methods. Without marked advances in computing power or methods, however, the difference will not be easily smeared out to make investigations of slow dynamics in current and/or more complex systems possible.

Section V. Chemistry of Glass

Figure 1 Thermodynamics occasionally prevailing over kinetics in glassmaking: the precipitation of a 1 mm devitrite crystal [$\text{Na}_2\text{Ca}_3\text{Si}_6\text{O}_{16}$] in a plate of window glass. *Source:* Photo courtesy Hervé Arribart and Saint-Gobain Recherche.

With the exception of the coloring substances added, batches have been determined for most of the history of glassmaking by the raw materials locally available without any means to characterize them chemically. In the seventeenth century, the extensive incorporation of lead, for instance, leads to distinguishing *flint* and *crown* glasses from differences in density and refractive index and not from chemical analyses (Chapter 10.10). Because chemistry lagged considerably behind physics throughout the ages, the modern notion of chemical composition was defined only in the early nineteenth century when analytical methods made its determination possible. Hence, the birth of modern chemistry dates back to only two centuries ago when the relevant elements were identified and their specific effects on processes and properties began to be investigated.

In this fifth section, chemistry will be dealt with from two different standpoints: one will be the various ways in which chemical composition can be tailored for specific purposes and the other how temperature changes and interactions with the environment not only modify the chemical composition of glass but may also alter its original nature through phase changes. As a starting point, T. Bach, R. Haus, and S. Prinz present the most common methods currently used to analyze chemical compositions – which are generally very rapid and can be used for tiny samples; in addition they present the special analyses performed in industry for B, Li, and F and for glass defects as well as standard tests for determining resistance to chemical attack (Chapter 5.1). In the following chapter, I. Veksler reviews the main types of thermodynamic equilibria depicted by phase diagrams relevant to glassmaking and the general effects of the most common elements on their topologies; that these diagrams are most important tools in the design of new compositions is pointed out as they may, for example, directly indicate that attempts at decreasing viscosity would result in unwanted increases in liquidus temperatures (Chapter 5.2). To provide such fundamental information, phase diagrams were traditionally determined from time-consuming quenching experiments (Chapter 10.11). Thermodynamic modeling of phase equilibria thus represents an interesting alternative. Thanks to better input data and improvements in thermodynamic models and computing power, the different kinds of procedures reviewed by G. Ottonello now allow much information to be obtained rapidly and at a reduced cost, especially for new, chemically complex compositions for which the amount of experimental work to be done could be really substantial (Chapter 5.3).

Although vitrification is the general goal of the glassmaker, incipient crystallization is not always avoided (Figure 1) when it is not purposely triggered to synthesize glass ceramics (Chapters 7.11 and 8.5). The theories of crystal nucleation and growth, and the problems they

are still raising, are thus directly relevant to the glassmaker. They are reviewed by E. Zanotto, J.W.P. Schmelzer, and V.M. Fokin in relation to such other important features as the validity of the Stokes–Einstein–Eyring equation to describe the diffusion of elements required for growing a crystal (Chapter 5.4). Equilibria with gaseous phases must also be considered in industry, where the topic is directly relevant to fining, as well as in the earth sciences where volatile solubility increases so strongly with pressure that at water can become a major component of deep magmas. As described by B.O. Mysen, volatiles dissolve as either reactive or nonreactive species, which, depending on temperature and composition, can affect properties and structure at low concentrations: hydroxyl $[\text{OH}^-]$ and carbonate $[\text{CO}_3^{2-}]$ ions produced by solution of water and carbon dioxide cause, for example, network polymerization and depolymerization, respectively (Chapter 5.5).

Along with melting reactions within the batch, redox interactions of the glass components with the atmosphere or the tin bath in the float process (Chapter 1.4) are of great concern for the glassmaker, in particular with respect to color (Chapter 6.2). Redox reactions are of two kinds depending on whether the system may be considered *closed*, in which case the relevant length and time scales are small, or *open*, in which case the evolution is controlled by interactions with the environment. In both cases, the evolution of the system is determined by the chemical potentials of the relevant oxides under the temperature, pressure, and oxygen fugacity conditions of interest. These potentials can in principle be predicted from *Ellingham diagrams*, as explained by R.F. Cooper, but many reaction mechanisms may operate with different kinetics, so diffusion of oxygen to or from the melt is not necessarily the fastest. Competing mechanisms do exist, such as rapid diffusion of network modifiers toward the surface along with a counterflux of electron holes, whose relative importance varies with temperature in ways that do not necessarily lead to the lowest Gibbs free energy but ensure instead its most rapid decrease such that the systems may end up trapped in a metastable state (Chapter 5.6).

The acid–base properties of glasses are another extensively discussed topic because silicate melts have long been viewed as mixtures of *acidic* SiO_2 and *basic* metal oxides. Two difficulties must then be faced, however: first, these acid–base interactions are closely intermingled with redox reactions, and second, a thermodynamic acid–base scale analogous to pH cannot be designed for *associated* liquids lacking analogs of H^+ and OH^- ions, where it may even be problematic to know which oxide is the acid and which is the base. The concept of optical basicity was formulated to circumvent these difficulties and provide an a priori scale for dealing with these reactions. As defined by J. Duffy, this scale first relied on shifts

in the UV frequencies of Pb^{2+} and Tl^+ ions considered as probes of the Lewis electron donor character of oxygens determined by the overall cation environment and then refined in terms of a simple relationship with the density and index of refraction; also discussed are implications in terms of electronegativity and molecular orbital theory and applications to slags, borates, fluorides, or sulfides (Chapter 5.7).

Probably the first use made of chemical changes within the material came from the realization in 1909 that some glasses act as semipermeable membranes through which ions can be exchanged between two solutions. Predating shortly the concept of pH, this discovery of the *glass electrode* provided a means to determine acid–base titration curves from the variations of the emf measured between the solution of interest and a reference solution. From these early experiments described by A.A. Belyushtin and I.S. Ivanovskaya, the pathway to the modern pH meter was short; although the instrument can measure not only pH but also the activity of monovalent cations and redox potentials, its theory has not been fully worked out yet because of the basic problems raised by the complex nature of the hydrolysis/condensation reactions and interdiffusion phenomena occurring within the glass membrane and near the glass–solution interface (Chapter 5.8).

For any redox couple, the most fundamental parameters are the redox potential and its dependence on temperature and composition. For melts in which the ionic conductivity is high, the voltammetry experiments described by C. Rüssel allow these potentials to be determined along with oxygen activities and even diffusion coefficients of polyvalent ions; as for impedance spectroscopy measurements, they are especially useful for studying corrosion phenomena (Chapter 5.9).

Corrosion is an important practical issue because contact of hot glass with molds and fiberizing plates is, for

example, required in the production of containers and fiber glass. Under usual redox conditions, corrosion represents oxidation and dissolution of the metal by the glass. The first step in metal/glass interaction is wetting, followed or not by sticking, which is favored by oxidized metal surfaces. The important parameters determining these interactions are thus temperature, oxygen partial pressure, metal and melt compositions, redox potentials, and also the surface condition of the substrate. From their review of the mechanisms at play in these phenomena and of their dependence on metal composition, C. Petitjean et al. conclude that passivation of the metal surface by an oxide layer is desired for reducing corrosion; as actually observed for Cr- and Ni-bearing superalloys, however, the condition is that the oxide must have a very low solubility in the melt to ensure the stability of this layer (Chapter 5.10).

Finally, the celebrated chemical inertness of glass is not absolute. Water attack is a potential problem as soon as a glass piece has been fabricated, explained by M.-H. Chopinet et al. who describe the two fundamental types of ion exchange involved in *acidic* and *basic* weathering as well as the precautions to be taken to protect newly made flat and container glass from degradation (Chapter 5.11). Much more severe corrosion can take place over long periods as exemplified by the complete weathering of natural glasses in seawater (Chapter 7.3). A noteworthy feature is then the formation of a gel layer at the water–glass interface, which slows down markedly the rate of the reaction and is usually interpreted as a complex interdiffusion zone between the pristine glass and the corroding solution. However, the chemical analyses now made at a much higher spatial resolution presented by R. Hellmann point to more complex mechanisms involving instead coupled interfacial dissolution/precipitation reactions (Chapter 5.12).

Chemical Analyses and Characterization of Glass

Thomas Bach, Reiner Haus and Sebastian Prinz

Dorfner Analysezentrum und Anlagenplanungsgesellschaft mbH (ANZAPLAN), Hirschau, Germany

1 Introduction

During millennia glassmakers displayed considerable skill to distinguish empirically various kinds of raw materials and, thus, to ensure consistent production at a time when chemistry was basically nonexistent (Chapter 10.2). Real advances in glass technology have then paralleled and heavily relied on progress in chemical analysis (Chapter 10.11). It is, for instance, no coincidence that modern glassmaking began once alkali and alkaline earth elements were identified at the beginning of the nineteenth century. Likewise, innovation in optical glass at the end of the last century would have been impossible without knowing new elements such as barium or strontium and having accurate ways of analyzing them.

Diversity is in fact a hallmark of both man-made and natural glasses. Although the compositions of the former are generally not very complex, the variety of elements introduced to ensure specific properties is now so large as to require the feasibility of quick and accurate analyses for all of them. This situation holds especially true for highly optimized processes where compositional variations caused by apparently innocuous changes in raw materials can cause real fabrication problems (Chapter 1.2). As for natural glasses, whether formed on Earth (Chapter 7.2) or in the solar system (Chapter 7.1), they have generally more complicated compositions with about 10 *major* oxide components (i.e. with abundances greater than 1 wt %) whose proportions vary widely. Besides, the concentrations of many *trace* elements must also be known because they represent valuable sources of information on the origin and geological history of these glasses. They

are even relevant to archaeometry, as exemplified by the manner in which neolithic trade routes can be reconstructed from chemical analyses of obsidian artifacts (Chapter 10.1).

Hence, the goal of the present chapter is to review the most common methods currently used to analyze glass chemically and to describe which are most appropriate for major, minor, or specific elements. Analytically, the main steps involved in sample preparation and analysis are depicted in Figure 1 where the acronyms refer to the methods listed below. Some of them have already been briefly presented in the context of electron microscopy (Chapter 2.3), whereas many have a physical basis similar to those reviewed for determining glass structure (Chapter 2.2) because they also make use of rays emitted by the sample when subjected to an electromagnetic radiation or a beam of particles.

In structural studies, however, interest is primarily laid on spectral features pertaining to interatomic bonds, which are in contrast a nuisance in analyses of chemical compositions. In other words, in these analyses, the elements of interest must be probed with as little as possible interferences from their neighbors, which shift and broaden spectral bands (the so-called matrix effects). In practice, this goal is achieved at energies high enough to induce transitions between the electronic energy levels of inner orbitals. Element concentrations are then determined more or less directly from the recorded intensities of the transitions induced by X-rays, electron beams, or also very high temperatures.

Although a great variety of such spectroscopic methods have become available thanks to the small amounts of sample needed and their rapidity, automated nature, and thus reduced cost, the good old gravimetric methods will be mentioned first. Not only are they still used for characterizing the important glass property of acid, alkali, and hydraulic resistance, but they are in the last resort the only methods

yielding absolute results with a high accuracy, so they remain, directly or not, at the basis of the working standards required by modern methods. Attention will then be paid to X-ray fluorescence, inductively coupled plasma methods, atomic absorption spectroscopy, and electron microprobe analysis and secondary ion mass spectroscopy. Next the chapter will discuss the particular analytical problems raised by boron, lithium, fluorine, and iron. Finally, the chapter will conclude with determinations of the resistance to chemical attack and of glass defects.

List of Acronyms

AAS	atomic absorption spectroscopy
F-AAS	flame atomic absorption spectroscopy
HG-AAS	hydride generation atomic absorption spectroscopy
G-AAS	graphite atomic absorption spectroscopy
EDL	electrodeless discharge lamp
EPMA	electron probe microanalysis
ETV	electrothermal vaporization

HCL	hollow-cathode lamp
IC	ion chromatography
ICP-OES	inductively coupled plasma optical emission spectroscopy
ICP-AES	inductively coupled plasma atomic emission spectroscopy
ICP-MS	inductively coupled plasma mass spectrometry
ISE	ion-selective electrode
LA	laser ablation
LIBS	laser-induced breakdown spectroscopy
SEM-EDS	scanning electron microscopy with energy-dispersive X-ray spectroscopy
SIMS	secondary ion mass spectrometry
XRF	X-ray fluorescence
WDXRF	wavelength-dispersive X-ray fluorescence
EDXRF	energy-dispersive X-ray fluorescence
μ-XRF	micro-X-ray fluorescence
UV-Vis	ultraviolet-visible spectrometry

2 Gravimetry and Glass Digestion

As designed in the nineteenth century, gravimetric methods have long been the only ones available to determine chemical compositions. They rely on dissolution of samples in appropriate solvents followed by titration of the resulting solutions with adequate reagents under well-defined concentration or pH conditions and finally weighing of the dried precipitates obtained [1]. As early illustrated in the nineteenth century by determinations of atomic masses, their accuracy can be extreme because weights are the only quantities measured so readily with relative errors lower than 1 ppm.

For SiO₂ analyses, samples are, for instance, digested in Na₂CO₃, and the silica precipitated by addition of hydrochloric acid is then determined gravimetrically. In this case, however, concentrations are systematically underestimated because not all silica will precipitate, leaving a small portion of silicic acid in solution in the highly acidic range. The silicic acid in solution can be quantified by photometry. But these methods now suffer from their time- and labor-intensive nature – especially because a single element can be dealt with at a time – along with the big samples of the order of several grams required. These drawbacks have thus led them to be generally phased out by modern techniques.

As described below, they do remain used for a few elements and for the evaluation of mass loss through determination of acid and alkali resistance. Another reason why glass dissolution must be mentioned is that samples are still analyzed as solutions in a number of important

methods. Hydrofluoric acid (HF) is the only acid that readily dissolves oxide glasses. Digestion is performed either in a platinum crucible open to the atmosphere or, to minimize cross contamination, in a closed recipient, for instance, placed in a microwave oven where higher temperatures and pressures allow for shorter digestion times. As indicated by Eqs. (1) and (2), HF digestion of silicon and boron leads to formation of volatile SiF₄ and BF₃, which causes lower than expected findings in the analysis:

Trace amounts of boron can be captured in the solution with complexing agents. The remaining fluorides are evaporated at elevated temperatures by addition of high-boiling mineral acids such as H₂SO₄ or HClO₄. The presence of sulfuric acid prevents a dry substance from being obtained when HF is evaporated completely, whereas insoluble fluorides are transformed into sulfates. If CaO, PbO, or BaO is present in the glass, HClO₄ is required to avoid the formation of hardly soluble sulfates that could not be analyzed. For P₂O₅-bearing glasses, the phosphorus content can be underestimated because this element is a *fugitive* constituent at elevated temperatures.

3 X-Ray Fluorescence

3.1 General

For major elements, the main advantages of X-ray fluorescence (XRF) analysis are its high speed and reproducibility down to concentrations as low as 100 mg/kg or even less [2, 3]. In addition, XRF is well suited for glasses (Table 1) and represents one of the few methods capable of direct, accurate analyses up to 100 wt % without sample dissolution.

Upon interaction with X-rays of appropriate energies, an inner electron of an element is ejected and replaced, depending on atomic mass number, by another from a higher energy level of another inner shell (e.g. K_α transitions between K and L orbitals, K_β transitions between M and K, and L_α transitions between M and L). In all cases, these transitions give rise to an emission of X-rays whose wavelengths are generally lower than that of the exciting radiation. The wavelength λ (or frequency ν) of this XRF is characteristic of each atom. Because the frequency is simply related to the energy E emitted by the relationship $E = h\nu$ (h , Planck constant), it can be detected and recorded in two different ways as made in structure determinations (Chapter 2.2). In the first, the X-ray intensity is measured as a function of the frequency

Table 1 Reproducibility of XRF analyses (wt %).

XRF	Al ₂ O ₃	Fe ₂ O ₃	TiO ₂	CaO	MgO	K ₂ O	Na ₂ O	SiO ₂
Average value	0.504	0.0585	0.023	9.12	4.27	0.332	13.02	72.33
SD	0.005	0.0002	0.001	0.01	0.02	0.004	0.01	0.02
RSD	1.02	0.39	2.90	0.17	0.39	1.27	0.09	0.03

Average, standard deviation (SD), and relative standard deviations (RSD) for 10 analyses of a float glass sample.

(or wavelength $\lambda = c/\nu$, where c is the speed of light) after being diffracted by a crystal according to Bragg's law ($2d \sin \theta = n\lambda$, where d is the relevant interplanar spacing). In contrast to such *wavelength-dispersive* analyses (WDXRF), the X-ray intensity can alternatively be measured as a function of energy at a constant angle from the sample in *energy-dispersive* analyses (EDXRF). The former spectrometers can quantify elements from Na to U (wavelength 1–0.01 nm), whereas the latter do it from B to U (6.7–0.01 nm).

Sample preparation is the same in both cases. If the specimen has a planar surface, it has to be polished and reduced to the 40 mm size of the sample holder. Glass specimens must be freshly prepared to avoid glass corrosion, which would cause sodium depletion on the glass surface (Chapter 5.11). They are cut, milled, or polished and can be directly analyzed with regard to the main elements, no further sample preparation (digestion) being required. Measurements can be carried out within a few minutes with concentrations as low as 50 mg/kg depending on calibration standards. Alternatively the glass can be ground down to a grain size of about 100 μm , mixed with lithium tetraborate and melted at 1300 °C to yield a bead that can then be analyzed directly.

Usually approximately 20 certified reference standards are required for a careful cross-checked calibration.

3.2 Wavelength-Dispersive X-Ray Fluorescence

In wavelength-dispersive X-ray fluorescence (WDXRF) analyses, the fluorescence signal is diffracted according to Bragg's law by a single-crystal analyzer. Because the angle of incidence is fixed, different diffraction angles represent different wavelengths, which are recorded by a scintillation counter and a flow proportional counter. Today available WDXRF instruments have an additional semiconductor detector for analysis of major elements to shorten measurement times. Various diffracting crystals are used (e.g. LiF220; LiF200; Ge111), now including even organic ones (thallium acid phthalate [TLAP], pentaerythritol [PET]) and the so-called layered synthetic microstructures (LSMs), which are made up of alternating layers of elements of high and low atomic numbers. These

alternating layers of high- and low-density materials simulate atomic planes in crystalline materials and the spacing between them (LSM Ni/C) and are used for elements of the second period, ideally allowing the quantification of elements from boron to uranium. For light elements (B, C, N), XRF is easily absorbed by the sample itself, so the radiation emitted strongly depends on the glass surface and preparation method. Only in rare cases can boron be detected and determined in a reproducible manner. Boron and lithium are two elements that are not quantifiable by XRF, which is why lithium tetraborate can be used for preparing the analyzed beads. For fluorine and elements of higher atomic numbers, an increased reproducibility can in contrast be achieved, which makes WDXRF ideally suited for production control.

3.3 Energy-Dispersive X-Ray Fluorescence

In energy-dispersive X-ray fluorescence (EDXRF) the sample emits a secondary characteristic fluorescence radiation, which is analyzed by a semiconductor detector simultaneously discriminating and counting all photons by energy. Spectrometers can thus have a significantly more compact design than for WDXRF (cf. Chapter 10.1). A lower power X-ray tube is then used, however, so that fewer atoms are excited and the resolution is reduced because of more pronounced line overlap especially for the light elements Na, Mg, Al, and Si. In short, modern EDXRF instruments are capable of analyzing glass test specimen at high speed, but WDXRF is recommended instead if reliable analyses of both major and minor elements are needed (e.g. Na or Fe in silica sand).

4 Inductively Coupled Plasma Methods

4.1 General

Since its introduction in 1975 under the name of inductively coupled plasma atomic emission spectroscopy (ICP-AES), this method has gained wide acceptance [4]. The sample is digested, generally in an HF solution before the solution is nebulized into an argon stream that

transfers it into a plasma torch where it is dried immediately, atomized, ionized, and excited at temperatures up to 10,000 K. In a few seconds the electromagnetic radiation spontaneously emitted is analyzed from about 150 to 800 nm by one or several semiconductor CCD detectors. Because the spectrum also includes ion emission lines, the technique is now better termed inductively coupled plasma optical emission spectroscopy (ICP-OES). Alternatively, the atoms/ions formed can be transferred into a mass spectrometer for analysis. With inductively coupled plasma mass spectroscopy (ICP-MS) method, one can in addition discriminate isotopes of the same element from their mass differences.

Alternatively, glass samples can be investigated directly if the sample is vaporized via electrothermal vaporization (ETV), laser ablation (LA) with nano- or femtosecond pulses, or laser-induced breakdown spectroscopy (LIBS) (see below). Thanks to the high sensitivity of inductively coupled plasma (ICP), only tiny amounts of sample material have to be weighed out, which results in higher relative weighing errors and lower recoveries.

4.2 Inductively Coupled Plasma Optical Emission Spectrometry

The major advantages of the method are (i) a high sensitivity so that trace elements can be analyzed down to 0.1 mg/kg; (ii) analyses done very rapidly thanks to the simultaneous detection of all element lines at several wavelengths for each of them; (iii) internal standards used to correct fluctuations of plasma temperature, Ar stream, and viscosity; and (iv) high sample throughput (40 samples/h) when recording the entire spectrum. There are of course disadvantages: (i) digestion of solids (glass) is generally required, in which case Si and B analyses are not possible if HF is used because of element losses into the gas phase; (ii) dilution errors result in a considerably lower reproducibility for the main elements compared with XRF; (iii) the increased effort required for determinations of alkali elements because of the alkali effect described below; and (iv) considerably higher investment and operating cost than for competing methods such as F-AAS.

In modern glass analytics the widely used sequential ICP spectrometers with photomultiplier tubes are no longer used. In specialized laboratories Paschen–Runge spectrometers are preferred because a high spectral resolution is required, which does not allow for a compact design. Thanks to their lower production costs and compact design, echelle spectrometers are nowadays the most common ICP design [4].

Most ICP-OES spectrometers allow for both radial (side-in) and axial (end-on) measurement without modification of the instrument setup but at the expense of sensitivity. Purely radial or axial spectrometers do not

require optical mirrors and do not have losses in sensitivity. Some instruments offer the possibility to carry out axial or radial measurements by changes in torch setup. The quantification limit is ten times lower with an axial than a radial geometry since the detector captures ions along a greater optical pathway. On the other hand, the axial design leads to an increased perturbation of excitations, which results in a pronounced tendency for recombination of ionized alkali elements to alkali atoms (*the alkali effect*). If lithium is measured in the presence of sodium, an equilibrium state exists in the plasma between lithium atoms and ions. If a lithium atom emission line is selected for quantification and if a considerable amount of other alkali elements is present in the sample (e.g. Na), then these other alkalis are also ionized. By recombination of ions with electrons in the plasma, the equilibrium shifts toward Li atoms so that too high Li concentrations are obtained if a lithium atom emission line has been selected for calibration. On the other hand, the axial setup may lead to a deposition buildup, which affects the argon stream and reduces the lifetime of the torch.

In general ICP-OES is well suited for the determination of trace elements in glass because its limit of quantification is considerably lower than that of F-AAS. The same applies to the system that can be fitted to an ICP-OES for the separation of hydride-forming elements in the gas phase. Lower limits of quantification can be achieved thanks to an improved signal-to-noise ratio; typically, however, this is not required in glass analytics.

Owing to the analytical importance of both techniques, it is useful to compare the results obtained with XRF and ICP-OES for ten analyses of the same float glass (Tables 1 and 2). The relative standard deviations of the main elements are smaller with the former than with the latter. Deviations in Na₂O content are due to the alkali effect, which has not been corrected here because only the precision was of interest. For float glass, analyses must be performed on the “air” face except for tin for which the so-called tin count is of course determined on the tin side. Unfortunately this determination is not standardized. Because it depends on the choice of the excitation conditions, measurements made in different laboratories with different analytical equipment and instrument settings are not directly comparable.

4.3 Inductively Coupled Plasma Mass Spectroscopy

In a more sensitive method, the optical spectrometer of ICP-OES is replaced by a mass spectrometer whereby the ionized atoms are accelerated and deflected by magnetic and electric fields [5–7]. The ions are then discriminated according to their mass-to-charge ratio when they

Table 2 Reproducibility of ICP-OES analyses (wt %).

ICP-OES	Al ₂ O ₃	Fe ₂ O ₃	TiO ₂	CaO	MgO	K ₂ O	Na ₂ O
Average value	0.426	0.0520	0.017	8.92	4.40	0.249	12.04
SD	0.007	0.002	0.001	0.214	0.195	0.008	0.243
RSD	1.73	3.71	3.79	2.40	4.44	3.34	1.88

Average, standard deviation (SD), and relative standard deviations (RSD) for 10 analyses of the same float glass sample as in Table 1. Quantification of SiO₂ not possible because of HF digestion.

hit the collectors where the ion fluxes give rise to small electric currents that have to be considerably amplified to yield a mass spectrum. The limits of quantification are about one thousand times lower than for ICP-OES, but the much higher cost of the equipment markedly restricts its uses in industrial glass analytics. The main application is the monitoring of the boron content down to 0.05 mg/kg in the high-purity quartz used for the production of silica crucibles serving for growing Si crystals with the Czochralski method for the semiconductor industry.

In contrast, the unique capabilities of ICP-MS are extensively exploited in fundamental research. Work done on extraterrestrial and geological glasses (Chapters 7.1–7.3) is in particular taking advantage of the possibilities of analyzing tiny or highly spatially resolved parts of samples through LA and of measuring accurately even isotope compositions [8]. In these analyses problems are raised by different ionic species that have the same mass, e.g. ³⁸Ar¹H and ³⁹K. To eliminate such *isobaric* interferences, the so-called collision and reaction cells are used whereby ³⁸Ar¹H⁺ can, for instance, be split by collisions with hydrogen, leaving ³⁸Ar, which is then easily distinguished from ³⁹K.

5 Atomic Absorption Spectroscopy

The development of ICP-OES has restricted the use of atomic absorption spectroscopy (AAS) to determinations of trace concentrations of coloring (Ni, Cr, Mn, Co, Cu, V, Fe, Mo) or environmentally and food-relevant (Pb, Cd, Ba, As, Sb, etc.) elements as prescribed by industry standards. The apparatus consists of a high-temperature atomizer unit, an element-specific radiation source, and a detector [9]. The concentration of the element studied is determined from the intensity ratio between the primary beam (*I*₀) and the radiation measured for the sample (*I*), which is introduced as a solution, dried, and atomized.

High temperatures are obtained in the atomizer with the flame of a burner (F-AAS) or a graphite furnace (G-AAS) with which concentrations down to 1 mg/kg for F-AAS and 1 µg/kg for G-AAS can be measured,

respectively. In fact, F-AAS is more reliable than ICP-OES and is less affected by element interferences because it usually involves hollow-cathode lamps (HCL), which are element specific because they consist of a cathode in the form of a hollow cylinder containing the element of interest. A special form of the HCL is the electrodeless discharge lamp (EDL). This lamp has a high radiance and a low spectral linewidth. Thanks to lower detection limits, it is best suited for elements such as As, Se, and Te.

Either an acetylene/air (*T* = 2300 °C) or an acetylene/nitrous oxide mixture (*T* = 2700 °C) as fuel gas is used depending on the testing purpose. Almost all elements can be determined without interferences and at good sensitivity. An advantage of F-AAS is the possibility of determining alkalis in the emission mode because these elements emit characteristic lines when thermally excited. This feature will make the use of expensive HCL unnecessary. Contrary to ICP-OES the determination of characteristic emission lines takes place at considerably lower temperatures of 1500–2700 °C. This means that predominantly atomic emission lines are observed, which will not bias the analysis, whereas in ICP analysis both atomic and ionic emission lines occur, causing the aforementioned phenomenon of ionization interference.

The main drawback of all AAS methods is the sequential mode of measurement, which requires frequent lamp changes since simultaneous measurements are not possible with HC and ED lamps.

To avoid this limitation, a xenon short-arc lamp (Chapter 6.9), which is a continuously emitting light source, can be employed and makes it possible to cover the entire spectral range of AAS. The photomultiplier detector used in the AAS so far has been replaced by a CCD detector, which has been regularly employed in ICP-OES equipment for years. These detectors are not as sensitive as photomultipliers, but this disadvantage is more than compensated by the high radiation intensity of the xenon short-arc lamp. These two innovations allow for simultaneous detection of absorption spectra, which in turn result in an improved linearity and signal-to-noise ratio and lower limits of quantification. The background

noise of the CCD detector is of course not considered in the actual absorption measurement.

6 Microprobe Analyses

6.1 Electron Probe Microanalysis

With electron probe microanalysis (EPMA), also termed electron microprobe analysis (EMPA), the chemical composition of a sample is determined from the wavelengths and intensities of the X-rays emitted upon bombardment of its surface by electrons accelerated at energies typically ranging from 5 to 30 keV [10, 11]. The electrons are released from a glowing tungsten filament or some other source, accelerated under vacuum in an electric field toward the anode and focused by an electromagnetic system of lenses as a spot of a few microns onto the sample surface, which must be highly polished and usually coated with carbon or gold to prevent electrical charging. The element-specific X-ray photons emitted are then detected and analyzed with either an energy-dispersive (EDS) or a wavelength-dispersive (WDS) X-ray spectrometer as described above and in Chapter 2.3. The latter configuration compares favorably with standard scanning electron microscopy with energy-dispersive X-ray spectroscopy (SEM-EDS) systems in terms of general sensitivity, spectral resolution, detector dead time, analysis of light elements, and risks of erroneous interpretation of qualitative spectra.

Although EPMA is a quick, fully quantitative method for all elements from B, it is not much used in industry where XRF is generally preferred. In addition to not being appropriate for analyzing trace elements, its drawbacks are the need of preparing highly polished, coated sample surfaces, of calibrating the instrument with appropriate standards to take into account specific matrix effects, and of adopting special procedures (low voltage and rastering of the electron beam on the sample) when analyzing alkalis and other elements prone to volatilization under the electron beam. But a major advantage is the visualization of the sample, which makes it possible to select a particular point of the surface for analysis. This is the reason why EPMA is extensively used in earth and materials sciences where detailed analyses of heterogeneous samples have to be routinely made. Although EPMA is in principle not sensitive to the redox state of an element, procedures have been designed to overcome the problem as made for iron in glasses [12].

6.2 Secondary Ion Mass Spectrometry

Alternatively, a sample surface can be bombarded by a focused beam of ions under a very high vacuum. Typically less than 1% of the atoms of the disorganized surface of the sample are then sputtered as *secondary ions* that

can be collected and analyzed with a high-resolution magnetic sector mass spectrometer, which thus discriminates between the various isotopes of a given element [13, 14]. Different instruments have been designed on this basis for specific applications. Primary ions such as Ar^+ , Xe^+ , Cs^+ , $^{16}\text{O}^-$, or $^{16}\text{O}_2^+$ are commonly used at energies in the 4–12 keV range, the particular one selected depending on factors such as the desired size of the primary ion beam, which ranges from 10 nm to 1 μm , and the nature of the sample investigated; oxygen and cesium ions are, for instance, recommended for analyzing electropositive and negative elements, respectively. Analyses as a function of penetration depth can also be performed with a resolution of 1 nm in the so-called dual-beam mode whereby the sample surface is continuously atomized with an ion beam (usually Cs^+) while a second ion beam is used to investigate the chemical composition of the newly created surface. This method does not always allow for a precise quantification, however, although quantitative results can be obtained by comparison with other samples.

As secondary ion mass spectrometry (SIMS) instruments are the most expensive analytical tools reviewed in this chapter, they are used only when a high spatial resolution is required for heterogeneous specimens or when the sample is too small to be analyzed by other methods as samples volumes as low as a few pg can be analyzed. The possibility of mapping chemical compositions is then especially valuable, as illustrated by a determination of the composition of a nonstoichiometric nepheline crystallizing as tiny dendrites at high degrees of supercooling in an aluminosilicate melt (Figure 2). Despite being the most abundant isotope of the most abundant element of this sample, ^{28}Si yielded in these analyses the lowest number of counts simply because of its low ionization efficiency under the primary $^{16}\text{O}^-$ ion beam used. For glasses, SIMS is in fact mainly the preserve of geo- and cosmochemistry especially since analyses can be made for a variety of volatile species such as H_2O or CO_2 [16] and for trace elements down to the ppm level as well as for determinations of isotope ratios [8]. In glass analytics, the technique is in contrast restricted to the investigation of surface defects by chemical analyses made on the first few atomic layers.

7 Special Elements

7.1 Boron

All other methods for boron analyses require sample digestion. By gravimetry, the ground sample is mixed with sodium hydroxide, melted above 600 °C, and quenched. The sample is partially dissolved in water, and the solution titrated with HCl against bromocresol purple

Figure 2 Dendrites of a nepheline of composition $(\text{Na}_{0.7}\text{K}_{0.2}\text{Ca}_{0.07}\text{Fe}_{0.05})\text{Al}_{0.92}\text{Si}_{1.05}\text{O}_4$ visualized by enrichments in Na, K, Al, and Si in nanoSIMS analyses of an aluminosilicate glass partially crystallized at 850 °C. Residual glass enriched in Ca and Fe around the dendrites, from which wollastonite $[(\text{Ca}, \text{Fe})\text{SiO}_3]$ crystallizes upon further annealing. Source: Cochard [15].

$[\text{C}_{21}\text{H}_{16}\text{Br}_2\text{O}_5\text{S}]$. Addition of CaCO_3 then causes interfering ions to precipitate and allow them to be removed by filtration. The filtrate itself is titrated with a NaOH solution against a defined pH value. The B_2O_3 concentration can be determined in this way for glasses with B_2O_3 contents higher than 0.5 wt %.

Ultraviolet–visible (UV–Vis) spectroscopy is another method, which relies on the property of certain ions (e.g. Fe^{3+} , Mn^{3+}) to form colored complexes with organic reagents such as 2,2′-bipyridine $[\text{C}_{10}\text{H}_8\text{N}_2]$. According to Beer–Lambert law, the intensity of light absorption at the appropriate wavelengths then is proportional to the concentration of these ions. With suitable standards, a calibration curve can thus be set up in order to determine the concentration of unknown samples [17].

These colored complexes are prepared in two ways. For 0.01–2.5 wt % B_2O_3 contents, azomethine-H $[\text{C}_{17}\text{H}_{12}\text{NO}_8\text{S}_2]$ is used to form a yellow boron complex in the aqueous solution formed upon dissolution of the NaOH-melted sample. In the 0.01–1 wt % range, the complexing agent can be curcumin $[\text{C}_{21}\text{H}_{20}\text{O}_6]$, a red-colored complex. The sample is

first melted with Na_2CO_3 or with a 1 to 4–6 ratio with a low-melting Na_2CO_3 – K_2CO_3 mix and possibly also with flux such as NaNO_3 . After cooling the solid obtained is dissolved in HCl, some H_2SO_4 is added, and the solution is heated and dehydrated. Formation of rosocyanine (in dissolved state), $[\text{B}(\text{C}_{21}\text{H}_{19}\text{O}_6)_2]\text{Cl}$, is achieved upon addition of curcumin. Finally boron is determined with UV–Vis spectroscopy after dissolution of the product in a water–ethanol mixture.

The third common method for boron analyses is ICP–MS. Although HF digestion leads to formation of volatile BF_3 , which causes the analysis to be too low, trace amounts of boron can be captured in the solution with complexing agents. Boron concentrations lower than 0.1 wt % can be determined in this way. For higher contents, the sample must be digested in NaOH–KOH solutions, but the method has two limitations: like for all ICP–MS analyses, the solution must be highly diluted, which causes uncertainties in the actual dilution factor, and, in addition, boron may be the source of a memory effect by first diffusing into and at a later stage out of ICP tubes and container walls.

7.2 Lithium

Glasses containing trace amounts of lithium can be digested in HF. If their Li concentrations are high, a sodium peroxide [Na_2O_2] digestion is recommended. The highly saline solution must then be diluted before quantification by ICP-OES or F-AAS.

7.3 Fluorine

At concentrations higher than 0.1 wt %, fluorine can be quantified with WDXRF either directly, if the sample is flat, or ground and pressed as a pellet otherwise. At lower contents, ion chromatography can be used after soda and potash digestion of the sample at 800 °C and dilution of the quenched product in water. The fluorine anion takes a specific time to pass through the chromatography column so that the F concentration can be determined at the end of the column by a thermal conductivity detector. The quantification limit is 0.1 µg/l equivalent to 10 mg/kg in glass.

Another method relies on an ion-selective electrode, which consists of an active material, typically LaF_3 for F analyses, placed in contact with the same solution as prepared for ion-chromatography analysis. At the phase boundary an electromotive force (emf) builds up, which in principle follows Nernst equation and is proportional to the logarithm of the activity of F ions. As a difficulty, at elevated F levels, large changes of concentration correspond to small changes in emf only. In addition, ions such as Ca^{2+} , Al^{3+} , or Fe^{3+} form hardly soluble fluorides that escape analysis. To avoid this trouble, elements can be masked with buffer solutions so that they will not precipitate.

As a matter of fact, pyrohydrolysis is one of the methods with which interfering ions can be separated in F-content determinations. When the finely ground sample is heated in a tube furnace in an atmosphere of superheated water vapor, the volatile fluorides are released and fed into an absorption solution. Alternatively, sinter extraction can be used. The glass sample is melted in a Na_2CO_3 –ZnO mixture at 1000 °C. After cooling, the sample is dissolved in water and filtered, and the remaining carbonates are decomposed in HCl. The fluoride limit of quantification is 10 mg/kg.

7.4 Ferrous Iron

Iron redox ratios are of crucial importance in the production of white glass and also play a fundamental role in petrology. In academic research, extensive use is made of Mössbauer and XANES spectroscopies (Chapter 2.2) because these provide in addition detailed structural information on the local environment of Fe^{2+} and Fe^{3+}

ions, but these methods are of course inappropriate for routine chemical analyses. A standard procedure consists of determining the total iron content, for instance, by XRF or ICP-OES analysis, and then deriving Fe^{3+} contents from the measured Fe^{2+} .

The three methods commonly used for this purpose all involve UV-Vis spectrometry [18].

The simplest makes use of a glass plate with parallel faces of known thickness for which extinction at 1054 nm is determined. According to Lambert–Beer law, the extinction is a function of the extinction coefficient of Fe^{2+} , the length of the optical path, and Fe^{2+} concentration. For a given glass composition, the extinction coefficient must of course be determined independently.

In a second method, the specimen is digested in a mixture of HF and H_2SO_4 , and Fe^{2+} ions are then converted into a pink complex by addition of phenanthroline [$\text{C}_{12}\text{H}_8\text{N}_2$] whose extinction is determined at 510 nm. Preferably the whole procedure is carried out under an inert atmosphere to prevent oxidation of Fe^{2+} in air. Alternatively, however, the sample may be digested in air, provided the solution is stabilized with nitrilotriacetic acid [$\text{C}_6\text{H}_9\text{NO}_6$] and measured directly in polystyrene cuvettes cooled with ice.

8 Resistance to Chemical Attack

In spite of its celebrated chemical inertness, glass is actually attacked by a variety of liquids. In industry, it is of particular importance to categorize glass into different classes with respect to hydrolytic, acid, and alkali resistance.

8.1 Hydrolytic Resistance

Special glasses have been designed for the pharmaceutical and medical sectors where patients must be protected from container impurities that might end up in drugs (Chapter 7.7). The resistance against water of the glass of interest is thus tested with standardized procedures to determine to which of the five classes that have been defined it belongs. The test determines the rate of Na^+ ions released from the color change of an indicator when the resulting alkaline solution is neutralized with HCl.

For the interior surfaces of glass containers, a given volume of the specimen is filled with water of defined purity, covered with an aluminum foil, and subjected to a temperature program reaching a maximum temperature of 121 ± 1 °C for 60 minutes [19]. The dissolution of mainly alkali, alkaline earth, and silicon ions results in a pH increase. The resistance class is then determined from the amount of HCl used to titrate the solution against methyl red until a color change is observed.

The hydrolytic stability of soda-lime glass can be improved by a surface finish applied during production. To check whether a glass has been surface-treated, a previously examined specimen is filled with a 1 : 9 mixture of HF and HCl and filled again with water after subsequent cleaning. The glass is then classified as surface-treated if the new titrimetric values are five to ten times higher than the first ones.

In another test the effect of temperature on hydrolytic resistance is determined on 100 g of glass carefully crushed with a hammer and steel mortar. The powder is passed through a magnetic separator to remove traces of metals from the mortar. The test is then made on the 300–500 µm sieved fraction cleaned in acetone, weighed in a vessel of defined volume, and heated at 98 °C for 60 minutes and titration as described above. For resistance tests at higher temperatures, the procedure must be modified in that the selected 300–425 µm sieved fraction is autoclaved for 30 minutes at 121 ± 1 °C [20] under strictly controlled conditions.

Alternatively, alkali and alkaline earth elements can be determined spectroscopically and then converted to Na₂O equivalents. The results obtained for a F-bearing glass by different methods are compared in Table 3. The cation (Na, K, Ca) contents determined by ICP-OES have been converted into Na₂O equivalents and summed up to yield a value 74.8 µg/g that deviates considerably from that determined by titration (53 µg/g). The discrepancy is caused by fluorine ions, which act like an acid (HF) in an aqueous solution neutralizing hydroxyl ions formed in the presence of alkali and alkaline earth ions. When the measured fluoride is converted into

Na₂O equivalents (26 µg/g) and added to the titrated Na₂O equivalent of hydrochloric acid (53 µg/g), both results are similar. The example demonstrates that determination of the hydrolytic class by titration is problematic for F-bearing glasses although it is allowed by the standardized procedure.

For pharmaceutical glass the aqueous solution obtained during the investigation of the hydrolytic class has to be analyzed with regard to As content. According to currently valid pharmaceutical regulations, quantification has to be carried out via hydride generation atomic absorption spectroscopy (HG-AAS), although ICP-OES is similarly suitable for this purpose. In HG-AAS a quartz cuvette is put on the burner of the F-AAS. The sample is reduced in a liquid–gas separator by a reducing agent (NaBH₄). Thanks to the separation of the gas from the liquid matrix, a very low limit of quantification is achieved. The measurement is carried out in a sequential mode, which results in extended measurement times at high consumption of chemicals and sample material. With this technique, other elements such as Sb and Hg can be analyzed in glass after digestion.

8.2 Acid and Alkali Resistance

Acid resistance strongly depends on surface properties. For determining it, the test specimen is cleaned with water and 2-propanol, dried, weighed, placed into a PTFE net, and immersed into boiling HCl ($c_{\text{HCl}} = 6$ mol/l) without being in contact with the walls of the vessel. After six hours, it is removed, rinsed, dried, optically inspected with regard to visible changes, and finally weighed and classified into one of four acid resistance classes from the measured mass loss. A similar procedure is followed for alkali resistance with a three hour immersion in a caustic solution:

1 : 1 mixture of Na₂CO₃ ($c_{\text{Na}_2\text{CO}_3} = 0.5$ mol/l) and a NaOH ($c_{\text{NaOH}} = 1$ mol/l) solution at 110 °C [21].

8.3 Leaching of Pb and Cd

For glass hollowware in contact with food, the rates of release of lead and cadmium must be checked. For this purpose, the hollow glassware is filled with a 4% (V/V) acetic acid solution for 24 hours at 22 °C [22]. The rate of leaching is then determined from the concentrations of lead and cadmium as measured by ICP-OES, F-AAS, or any other equivalent method. Producers of lead crystal glass are meeting the required thresholds for Pb and Cd. Nevertheless demand for lead crystal glass is strongly decreasing, resulting in a limited number of producers.

Table 3 Comparison between hydrolytic-resistance tests made for a F-bearing glass as determined by ICP-OES, titration, and ion chromatography.

Element	ICP-OES	
	Concentration (µg/g)	Na ₂ O Equivalent(µg/g)
Na	32	43.1
K	4.9	3.9
Ca	18	27.8
Sum		74.8
Titration		
	V(HCl) (ml)	
	0.17	53
Ion chromatography		
F	16 (µg/g)	26

9 Analyses of Glass Defects

Reams or inclusions are among the most common glass defects. They account for high economic damage, so understanding their formation is very important to the glassmaker. They are caused either by impure raw materials, containing, for example, refractory heavy minerals, or by the glass-melting furnace or other parts of the plant (Chapter 1.2). They must appear at the glass surface to be investigated. In addition to SIMS described above, the following methods can be used.

9.1 Micro-X-Ray Fluorescence

In micro-X-ray fluorescence (μ -XRF), the X-ray beam is focused to a small diameter of typically 50–200 μm . One can thus analyze tiny spots on a sample identified by means of a camera either individually (“spotting”) or by applying a grid of individual measurement spots on a pre-defined area of the sample (“mapping”). This technique is typically applied in glass defect analysis. Inclusions of foreign particles (Al_2O_3 , ZrO_2) in the glass can deliver important information on the state of a glass-melting furnace or on contamination of raw materials, for instance, by heavy minerals (chromite, barite, etc.).

9.2 Laser-Induced Breakdown Spectroscopy

The other method is LIBS with which a highly energetic laser pulse vaporizes and atomizes the sample surface at a very small scale. The radiation emitted by the plasma formed is then analyzed with a spectrometer [23]. Important advantages of the method are that it requires very little or no sample preparation and that only a tiny amount of the sample material is removed in a layer-by-layer fashion. In addition, it is a very fast method that allows for a depth-resolved profiling of the chemical composition. Owing to instrument design, however, the spectrometer and laser are not in the same optical axis, which means that the intensity of the emitted radiation reaching the detector decreases when the penetration depth increases. Besides, the reproducibility of LIBS is often limited by variations in the laser spark and resultant plasma. One should take into account that LIBS is not suitable for bulk analysis of not perfectly homogeneous materials since only a very limited volume is probed.

9.3 Scanning Electron Microscopy with Energy-Dispersive X-Ray Analysis

For analyses of glass defects, a very precise quantification is in fact not required. If SEM-EDS has, for instance, a good spatial resolution of less than 1 μm , the sample

has to be sputtered, which is time consuming. In contrast, LIBS and μ -XRF have a lower spatial resolution of 50–200 μm , so they are suited best for determining heavier elements or bigger defaults.

For example, analyses of the glass defect shown in Figure 3 and made with SEM-EDS indicate a significant increase of the Al_2O_3 and ZrO_2 concentrations (Table 4). Since Al and Zr oxides are typical refractory materials used in the construction of glass-melting furnaces, one must conclude that the defect likely originated from the plant and not from the raw materials used.

10 Perspectives

EDXRF and AAS will likely take a leading role in analyses of industrial glasses. The former allows for quick analyses thanks to simultaneous element detection by solid-state semiconductor detectors, which is cost efficient with a compact design and a lower power X-ray tubes that are

Figure 3 Glass defect: streak in a float glass as seen and analyzed (Table 4) by SEM-EDS.

Table 4 Defect in a float glass as revealed by anomalous chemical analyses made by SEM-EDS.

Point	Na ₂ O	Al ₂ O ₃	SiO ₂	K ₂ O	CaO	ZrO ₂	BaO
1	10.71	1.12	72.99	3.37	5.77	0.00	6.04
2	10.64	1.27	72.64	3.39	5.82	0.00	6.23
3	9.82	10.32	68.13	4.99	2.39	0.68	3.68
4	9.86	12.39	66.76	5.28	1.84	0.69	3.18
5	10.40	15.69	63.04	5.66	1.32	0.88	3.01

Points 3, 4, and 5 within the glass defect.

less expensive than wavelength-dispersive instruments, which do yield a higher resolution. Taking into consideration the rapid advances made in detector technology (e.g. silicon-drift detectors requiring only Peltier instead of liquid-nitrogen cooling), one can even expect that their resolution will keep improving in the next generation of instruments.

On the other hand, almost all elements can be analyzed without interferences and with good sensitivity with AAS whose main drawback has been the sequential and, therefore, time-consuming mode of measurement caused by frequent lamp changes. The introduction of continuously emitting xenon short-arc lamps as light sources has helped to overcome this limitation at the same time that the use of CCD instead of photomultiplier detectors has greatly improved the efficiency of the instruments. As to the lower sensitivity of CCD detectors, it is more than compensated by the high radiation intensity of xenon short-arc lamps. These two innovations allow for simultaneous detection of absorption spectra, which in turn result in improved linearity and signal-to-noise ratio, in lower limits of quantification, and, of course, in timesaving benefits. In other words, AAS could regain in this way the situation it has lost lately at the expense of ICP-OES in systematic analysis of major elements, in which case it would no longer be restricted to determinations of trace concentrations of coloring (Ni, Cr, Mn, Co, Cu, V, Fe, Mo) or environmentally and food-relevant (Pb, Cd, Ba, As, Sb, etc.) elements. Whether or not this novel technique actually finds widespread use in glass analytics will thus be seen in a near future.

Finally, another striking feature of the evolution of chemical-analysis methods consists in the tremendous increase in spatial resolution: Accurate results can now be obtained for samples smaller than 1000 nm^3 , which are thus about 10^{18} times smaller than the specimens originally required by gravimetric methods (in analyses that are in addition performed about 1000 times faster). To take full advantage of such resolutions, however, it should not be overlooked that some specific preparation methods should in parallel be used for preparing the samples investigated in a way commensurate with the actual analytical resolution, as illustrated in Chapter 5.12 for corrosion reactions.

Acknowledgments

The authors thank A. Klier and M. Maier for kindly providing the XRF and ICP data of Tables 1 and 2, K. Holtman and R. Conradt for their thorough review of the

present chapter and helpful comments, G. Libourel for additional information, and J.-P. Cochard for the analyses of Figure 2.

5.2

Phase Equilibria and Phase Diagrams in Oxide Systems

Ilya Veksler

GFZ German Research Centre for Geosciences, Potsdam, Germany

1 Introduction

In glassmaking, phase changes are of fundamental importance since the process most commonly involves the melting of a mixture of solid starting materials (Chapter 1.1). Phase heterogeneities in glass (e.g. crystal inclusions, gas bubbles, etc.) are usually regarded as defects (Chapter 1.2), so glass-forming melts are usually kept at temperatures much higher than that thermodynamically needed to ensure complete melting. Special measures are then taken to avoid crystallization of the melt and/or its unmixing to immiscible liquid phases upon cooling. In contrast, the production of special types of glasses (e.g. turbid, opaque, opalescent) and of glass ceramics requires controlled formation of solid–liquid or liquid–liquid heterogeneous phase assemblages. In any case, whether nucleation of new phases (phase separation) should be avoided or controlled, an in-depth knowledge of crystal–liquid and liquid–liquid phase equilibria in specific glass-forming systems is crucial. Hence, phase diagrams displaying melting/crystallization relationships in temperature–composition (T – x) coordinates play the same fundamental role in scientific studies and production of glass as topographic maps in geography and navigation.

Although until the 1960s phase diagrams could be determined only experimentally, they did strongly rely on fundamental concepts of chemical thermodynamics as pioneered by J.W. Gibbs (1839–1903) and, in particular, on the phase rule. It is thus appropriate to begin this chapter with a brief review of the theoretical concepts on which phase diagrams are based. The different types

of diagrams resulting from varying mutual solubility between components in the solid and liquid phases are then described. Special attention is given to liquid immiscibility and liquid–solid phase separation in glass-forming systems, but liquid–gas equilibria will not be described in view of the very low solubility of volatiles in glass-forming melts at room pressure (Chapter 5.5). Finally, some examples of particular importance for glass-making are discussed in greater detail.

In preamble, however, we first note that the sluggishness of chemical reactions in viscous glass-forming systems generally prevents phase transitions from being observed by abrupt changes in physical properties. Ever since the beginning of the twentieth century, the quenching method has thus been used: a sample of a given composition is heated at an appropriate series of precisely measured temperatures, quenched, and observed under the microscope for detection of the very first occurrence of glass (at the *solidus* temperature) and the total disappearance of crystals (at the *liquidus* temperature). It goes without saying that the procedure is very tedious if experimental brackets of a few degrees are to be obtained. In industry, this is why it is common practice to run instead simultaneously a number of samples of the same composition in a gradient furnace (Chapter 5.1).

Additional experimental difficulties arise from the significant volatility of some elements (e.g. the alkalis), the high melting temperatures of some components (e.g. the alkaline earth oxides), or redox changes of transition elements such as iron (Chapter 5.6), which imply to control not only temperature but also the oxygen fugacity. Nevertheless, phase equilibria have been established with great care and accuracy sufficient for most practical and theoretical applications. Even complexities such as liquid unmixing was discovered as early as the 1920s in alkaline earth silicates in spite of the temperatures higher than 1600 °C at which it takes place [1]. In brief, phase

Reviewers: M. Roskosz, Muséum National d'Histoire Naturelle, Paris, France

A. Takada, Research Center, Asahi Glass Co. Ltd., Yokohama, Japan

diagrams are indispensable reference tools, so special compilations have long been available to glassmakers and ceramists, first as books [2] and now through electronic databases [3].

2 Thermodynamic Principles

2.1 Gibbs Free Energy

The macroscopic state of a glass-forming system can, in principle, be defined with little or no reference to microscopic states at the atomic and molecular level, but some discussion of molecular species and chemical bonds is practically unavoidable when thermodynamic methods are applied to systems with chemical reactions (Chapter 5.3). First and foremost, however, the importance of thermodynamic laws and their great usefulness in chemistry and materials science lie in their theoretical ability to predict the direction of chemical reactions and the stable state of a system of a given chemical composition at given pressure and temperature. With thermodynamic methods, one can predict the stable macroscopic state of the system, e.g. the nature and chemical compositions of stable solid, liquid, and gaseous phases, without needing to consider the previous macroscopic states and the processes that led to the final state of interest.

Laboratory experiments and technological processes are generally performed at constant temperature and pressure, e.g. one atmosphere. If the temperature is changed during the process, sensible measurements are usually done after the change is over, when the temperature has become uniform in all parts of the system. Systems without internal pressure and temperature gradients are called isobaric–isothermal. Stable macroscopic states and the direction of possible chemical reactions in such systems are predicted by the analysis of a thermodynamic potential, the *Gibbs free energy* (G), which is defined as

$$G = H - TS. \quad (1)$$

In Eq. (1) H is the enthalpy, which, under isobaric conditions, is equivalent to the loss or gain of heat (thermal energy) to or from the surroundings of the system; T is the absolute temperature; and S is the entropy of the system. Although G is measured in units of energy, the traditional name is somewhat misleading because the energy conservation law does not apply to G , so G differs from the internal energy U in that important respect. Alternatively, *Gibbs function* has been recommended to avoid the confusion, but the traditional term remains in broad use.

Because H , T , and S are all state functions, so is G . It quantitatively defines the equilibrium state of the system. As, for instance, caused by a pressure or a temperature

variation, a change in the state of a system results in a change of its Gibbs free energy ΔG , which in turn combines enthalpy and entropy changes, ΔH and ΔS :

$$\Delta G = \Delta H - T\Delta S. \quad (2)$$

Notably, in an isobaric system,

$$\Delta H = -Q = -T\Delta S_{\text{ext}}, \quad (3)$$

where Q is the heat transported from outside the system (hence the negative sign) and ΔS_{ext} is the external entropy change in the system surroundings. From Eqs. (2) and (3), it follows that

$$\Delta G = -T\Delta S_{\text{ext}} - T\Delta S = -T\Delta S_{\text{tot}}, \quad (4)$$

where ΔS_{tot} is the overall change of entropy within and outside the system. According to the second law of thermodynamics, any spontaneous, self-sustaining process must result in an increase of S_{tot} or, in other words, must have a positive ΔS_{tot} . Therefore, from Eq. (4), it follows that ΔG must be negative for spontaneous changes of state:

$$\Delta G = \Delta H - T\Delta S < 0, \quad (5)$$

so the stable macroscopic equilibrium state is the one with the lowest G at given pressure, temperature, and chemical composition.

Like H and S , the Gibbs free energy is an extensive (additive) variable. For a generalized reaction

its variation ΔG_r is defined as a sum of the Gibbs free energy of the products minus that of the reactants:

$$\Delta G_r = G_C + G_D - G_A - G_B. \quad (7)$$

The reaction spontaneously proceeds to the right toward the products if

$$G_C + G_D < G_A + G_B, \quad (8)$$

and in the opposite direction toward the reactants in case

$$G_C + G_D > G_A + G_B. \quad (9)$$

The reactants and products can be individual phases or components taking part in homogeneous reaction. At equilibrium, ΔG_r should be 0:

$$\Delta G = \Delta H - T\Delta S = 0. \quad (10)$$

Processes relevant to glassmaking mostly take place at high temperatures where the contribution of the product $T\Delta S$ is often significant and the sign and value of ΔG thus strongly depend on those of ΔS . For example, melting of a crystalline solid to an isochemical liquid is characterized by a significant and positive entropy change, ΔS_m . When crystals and melt are at equilibrium, $\Delta G = 0$ and a positive ΔS_m implies that melting is strongly endothermic (ΔH_m positive and large). It also follows that melting will be spontaneous at $T \geq \Delta H_m / \Delta S_m$.

2.2 Phase Rule

In multicomponent systems, the Gibbs free energy is expressed as a sum of partial molar energies (chemical potentials) of individual components, μ_a , multiplied by the number of moles of each component N_a present in the system. Thus, for a system with n components,

$$G = \sum_a^n \mu_a N_a. \quad (11)$$

The conditions for equilibrium in heterogeneous (multiphase) system require that all intensive variables (e.g. pressure, temperature, and chemical potentials of all the components) should be equal in all phases. Thus, in a system with n components and p phases,

$$T^1 = T^2 = T^3 = \dots = T^p, \quad (12a)$$

$$P^1 = P^2 = P^3 = \dots = P^p, \quad (12b)$$

$$\mu_a^1 = \mu_a^2 = \mu_a^3 = \dots = \mu_a^p, \quad (12c)$$

$$\mu_b^1 = \mu_b^2 = \mu_b^3 = \dots = \mu_b^p, \quad (12d)$$

...

$$\mu_n^1 = \mu_n^2 = \mu_n^3 = \dots = \mu_n^p. \quad (12e)$$

The set of equations implies a fundamental relationship between the number of independent intensive variables (degrees of freedom f), the number of components n , and the number of phases p in a heterogeneous multicomponent system:

$$f = n - p + 2. \quad (13)$$

This relationship is the *phase rule*. Its fundamental implication is that the maximum number of phases in a closed system at equilibrium cannot exceed $n + 2$ because negative values for f would be by definition meaningless. A physically viable system must contain at least one component. With pressure and temperature as the two independent variables in Eq. (13), the maximal number of phases in a single-component system thus is 3. The maximal assemblage of $n + 2$ phases represents an invariant ($f = 0$) phase equilibrium, which occurs at a unique combination of values of all intensive variables. None of the values can be changed without disappearance of at least one phase.

Although they have a considerable importance in earth sciences, the effects of pressure on crystal–liquid and liquid–liquid phase transitions and equilibria will not be considered in this chapter because technological processes, glassmaking included, are generally carried out at one atmosphere. If pressure is excluded from the list of intensive variables, the equation for the phase rule then takes the form

$$f = n - p + 1, \quad (14)$$

which will be used in the following discussions of phase equilibria diagrams.

2.3 Gibbs Free Energy of Mixing

From a thermodynamic point of view, a homogeneous solution is stable when its Gibbs free energy is lower than that of mechanical mixture of its components. The energy difference between the solution and the equivalent mechanical mixture is the Gibbs free energy of mixing ΔG_m . Mixing relationships between nonideal components, i.e. chemically interacting with one another, are often discussed in terms of the simple regular solution model, which assumes that the components mix completely at random even though they interact with a positive or negative enthalpy of mixing depending on whether the overall interactions are repulsive or attractive. Although the model is a crude approximation to real solutions relevant for glass-forming systems, it will illustrate nicely some fundamental principles of mixing and unmixing between components A and B.

Conventionally, the chemical composition of the system is expressed in terms of the mole fractions of the components x_A and x_B :

$$x_A = \frac{N_A}{N_A + N_B}, \quad (15a)$$

$$x_B = \frac{N_B}{N_A + N_B}, \quad (15b)$$

$$x_A + x_B = 1, \quad (15c)$$

where N_A and N_B are the numbers of moles of A and B in a given composition. Like any other type of Gibbs free energy of mixing, ΔG_m is made up of enthalpy (ΔH_m) and entropy (ΔS_m) terms:

$$\Delta G_m = \Delta H_m - T \Delta S_m. \quad (16a)$$

For an *ideal* solution, the former is zero and the latter is given by

$$\Delta S_m = -R(x_a \ln x_a + x_b \ln x_b), \quad (16b)$$

where R is the gas constant. Because mole fractions are lower than 1, the logarithm term is negative, and, therefore, ΔS_m is positive. As for the enthalpy of mixing, it is given by

$$\Delta H_m = \alpha x_a x_b, \quad (17a)$$

where

$$\alpha = NZE_{ab}, \quad (17b)$$

and E_{ab} is an interaction energy between components A and B, Z is the coordination number of the interacting

Figure 1 Binodal and spinodal in a binary system A–B. (a) Gibbs free energy (G) versus composition (x) curves for the consolute temperature T_c and two other temperatures either higher (T_1) or lower (T_2) than T_c . The spinodal is defined by the inflexion points s_1 and s_2 , the compositions of the immiscible phases A_s and B_s by those at which a line is twice tangent to the G curve. (b) Two-phase region $A_s + B_s$, binodal and spinodal in T – x coordinates.

components, and N is Avogadro's number. If α is negative, so are ΔH_m and ΔG_m , and the solution is stable at any temperature and composition. If the interaction parameter is positive, the balance between enthalpy and entropy terms (which oppose and favor mixing, respectively) changes with temperature. In Figure 1a, ΔG_m curves are plotted versus composition x at three different temperatures $T_1 > T_c > T_2$. At T_1 the G – x curve is concave, whereas at T_2 there are two minima and a local maximum in the middle. Between the minima, the original solution unmixes into two coexisting subsolutions A_s and B_s because the Gibbs free energy of the homogeneous phase is greater in that composition interval than that of a mechanical mixture of A_s and B_s . The positions of the minima along the x axis change with temperature, the compositions of A_s and B_s moving further apart with falling temperatures. In T – x coordinates, the loci of minima plot along a convex curve, the *binodal* (Figure 1b). The temperature T_c represents the maximum point of the binodal curve when two solutions merge into one, so both temperature and point are termed *critical* or *consolute*. In the context of the regular solution model,

$$T_c = \frac{\alpha}{2R}. \quad (18)$$

Therefore, measurements of T_c provide a means for evaluating the interaction parameter α .

The inflexion points s_1 and s_2 in the G – x curves (Figure 1a) are defined by the second derivative $(\delta^2 G / \delta x^2)_{T,P} = 0$. Their loci define in the T – x plot a convex curve, the *spinodal* (Figure 1b), which delineates two different mechanisms of unmixing (Chapter 5.4). In

compositional intervals between the binodal and spinodal, unmixing proceeds via nucleation and growth and is hampered by thermodynamic barriers associated with nucleation. The nuclei of a new phase are viewed as small aggregates of atoms formed by random compositional fluctuations δx . Compositional fluctuations smaller than a certain critical value produce increases of Gibbs free energy and are, therefore, thermodynamically unstable. In contrast, there is no thermodynamic barrier for phase separation within the spinodal region as the Gibbs free energy change is negative for an infinitesimal fluctuation. Kinetic limitations are the same for both mechanism of unmixing, however, because they arise from material transport and dynamic parameters such as diffusion rates and viscosity.

3 Basic Topological Types of Binary T – x Diagrams

3.1 General Remarks

Binary (two-component) mixtures including liquid (melt) among the phases are the simplest cases of systems relevant to glassmaking. As a matter of fact, they have a more general interest because atomic interactions have a mainly pairwise nature in oxide solutions (Chapter 2.8). In other words, one can consider that higher-order effects have only a small influence in ternary or multicomponent systems and that, at least qualitatively, information drawn from binary mixtures can throw valuable light on phase equilibria in more complicated systems.

The Gibbs free energy and the binodal and spinodal curves defined by the regular solution model are symmetrical along the x axis. These features are rarely observed in silicate and other glass-forming systems, however, where binodal curves are usually strongly asymmetric and imply more complex interactions between the components. In this respect, an important point is that both strongly positive and negative interactions result in phase separation. The difference is that the former causes unmixing whereas the latter yields formation of intermediate compounds. This contrast is typically observed in binary silica–metal oxide systems where liquid immiscibility is found on the SiO_2 -rich parts and compound formation beginning at SiO_2 contents ranging from 20 to 50 mol %. This observation does not contradict the aforementioned binary nature of atomic interactions. It indicates instead that interactions of silicon with other cations depend on its Q^n speciation (Chapters 2.1 and 2.4), being repulsive for $n = 4$ species and attractive for the lowest values of n .

Another fundamental feature is the existence or lack of long-range order in a phase. As a rule, element mismatch is of course much more easily accounted for in liquids

than in crystals, so mutual solubility is systematically higher in the former than in the latter. Consequently, complete miscibility in solid solutions is excluded in systems with limited melt miscibility. Likewise, intermediate compounds are not to be found in compositional regions of liquid immiscibility.

Depending on the mutual solubility of components in the liquid and solid phases and the existence or lack of reactions between the solids, the T – x phase diagrams of the binary systems fall into several basic topological types. Those types of diagrams and phase equilibria, which they illustrate, will now be discussed in the context of Gibbs free energy variations with temperature T and composition x expressed in molar units or, alternatively, in mass units for convenience in practical applications. In conventional binary T – x diagrams, temperature is plotted along the vertical axis at the right angle to the composition line. Compositions along the latter are plotted in bar-centric coordinates.

3.2 Complete Miscibility in Melt and No Solubility or Reaction Between Solids

Consider a generalized system of components A and B, which are completely miscible in the melt L and form the immiscible crystal phases A and B. At constant pressure, its Gibbs free energy is a function of temperature and composition, $G = f(T, x_A, x_B)$. In a G – x diagram (Figure 2), the Gibbs free energy G^s of the solid phase assemblage A + B varies with composition along the straight line connecting those of the crystalline phases G^A and G^B . The linear G – x relationship is characteristic for mechanical mixture of phases, which do not mix or react. The equation of the line is

$$G^s = x_A G^A + x_B G^B, \quad (19a)$$

or, because $x_A + x_B = 1$,

$$G^s = (G^A - G^B) x_A + G^B. \quad (19b)$$

A plot of Gibbs free energy of the melt G^L versus composition is a concave curve (Figure 2). The G – x diagram in Figure 2a thus represents the situation where the liquid is stable but the solid phases are not. This situation exists at temperatures above the melting points of crystal phases A and B. With decreasing temperature, the Gibbs energies of the solid phases and melt increase, but G^L increases faster than G^A and G^B because the entropy of the melt is greater. At some temperature T_2 (Figure 2b), the Gibbs energies of the solid and liquid phases for the pure component B become equal, so the solid B begins to crystallize. As temperature decreases, the melt in equilibrium with solid B becomes gradually depleted in this component. In a G – x diagram, the

equilibrium composition of the melt (L_1) is defined by the intersection of a tangent line drawn from the point G^B with the curve G^L (Figure 2c).

Below the melting point T^A of A, crystallization of this phase becomes possible on the left side of the diagram where the concentrations of this component in the melt are high and melts equilibrated with solids A and B are defined in the same way by tangent lines (Figure 2d). The loci of melt compositions in equilibrium with the solids A and B are represented in T – x space by two liquidus curves (Figure 2g). In a binary isobaric system, two-phase equilibria L + A and L + B are univariant. The curves intersect at a point of the invariant equilibrium L + A + B, the eutectic (point E in Figure 2e and g). Below the eutectic temperature T_E , the liquid phase is unstable because the Gibbs free energy of the solid assemblage A + B is lower than G^L at any bulk composition x (Figure 2f). The horizontal line going through the eutectic point E in Figure 2g is the solidus line. Below it, the system has totally crystallized.

3.3 Complete Miscibility in Melt and Binary Solid Solution

A binary system may include one or several intermediate compounds resulting from chemical association between the solids:

If an intermediate compound has a fixed composition or, in other words, is immiscible with other solid phases, it must melt at a fixed melting point either isochemically (congruently) to the liquid of the same composition or incongruently to a liquid of a different composition and another solid phase:

Phase diagrams with congruently and incongruently melting binary compounds are presented in Figure 3a and b. Congruently melting compounds, such as A_mB_n in Figure 3a, divide the diagram into two parts, which can be considered as independent eutectic-type subsystems ($\text{A} - \text{A}_m\text{B}_n$ and $\text{A}_m\text{B}_n - \text{B}$ in Figure 3a). Notably, eutectic points in adjacent subsystems (E_1 and E_2 in Figure 3a) are not at the same temperature because the stable coexistence of more than two solid phases with a liquid in an isobaric binary system does not comply with the phase rule.

In Figure 3b, the intermediate compound A_mB_n melts incongruently into the solid phase A and liquid L of composition P, which, in agreement with mass-balance considerations, is richer in component B than the solid A_mB_n . The invariant phase equilibrium $\text{A}_m\text{B}_n + \text{A} + \text{L}$ corresponds to the peritectic point P.

Figure 2 Binary system A-B with end members miscible only in the melt. (a–f) Gibbs free energies of the solid and liquid phases as a function of composition for temperatures decreasing from T_1 to T_6 . (g) Derived eutectic-type phase diagram (L = liquid, T_E = eutectic temperature).

Figure 3 Transformation of a two-eutectic system (a) into a peritectic system with a single eutectic (b) resulting from the incongruent melting of the intermediate compound A_mB_n (peritectic point P).

3.4 Complete Miscibility in Melt and Solid Solution

In case of complete miscibility between the components A and B in both liquid and solid states, the Gibbs energies of the binary melt (G^L) and solid solution (G^S) plot as concave curves in G - x coordinates. The changes of the relative positions of the curves with temperature are

illustrated by a series of G - x diagrams in Figure 4 from the highest temperature T_1 where the melt is stable in the whole range of compositions (Figure 4a) to T_6 where the solid solution is the single stable phase (Figure 4f). At intermediate temperatures T_2 - T_5 , the melt and solid solution coexist, and the equilibrium compositions of the liquid and solid phases L and S are defined by

Figure 4 Binary system with complete miscibility in both the solid and molten phases. (a-f) Gibbs free energies against composition at six decreasing temperatures. (g) Derived spindle-type phase diagram.

intersections of the curves G^L and G^S with a common tangent line (Figure 4c and d). The resulting T - x phase diagram features convex liquidus and concave solidus curves intersecting at the melting points of the pure components A and B (Figure 4b and g). But the $L + A_{ss}$ (or B_{ss}) two-phase fields of the solid solutions (ss) may have a more complex V shape and consist of two or even more segments (Figure 5b).

3.5 Complete Miscibility in Melt and Limited Miscibility in Solid Solution

If the enthalpy of mixing of the A-B solid solution is positive, the Gibbs free energy of the solid solution changes with falling temperature in the way illustrated in Figure 1 so, below the critical temperature T_c , the homogeneous binary solid solution splits in two coexisting solid subsolutions A_{ss} and B_{ss} . The equilibrium compositions of the phases in T - x coordinates plot along

the bell-shaped convex curve labeled as the binodal in Figure 1b (which is actually termed *solvus* for solid solutions).

Four basic topological types of T - x binary diagrams with limited miscibility in solid solution are presented in Figure 5. The differences lie in the shape of the liquidus curve and relationships between solidus and solvus. The liquidus curve slopes in one direction and has no inflection in Figure 4a and c, whereas the curve is V shaped in Figure 5b and d. The solvus and solidus do not intersect in Figure 5a and b, whereas they do so in Figure 5c and d. In Figure 5a and b, the melt crystallizes to the homogeneous solid solution S_s , which unmixes to the subsolutions S_{s1} and S_{s2} at lower temperatures. In Figure 5c and d the homogeneous solid solution does not exist at subsolidus temperatures. The phase relationships in solid solutions can be very complex, but they are relevant to glass-making only for production of glass ceramics, where they are critical to achieve the desired properties (Chapters 7.11 and 8.5).

Figure 5 From (a) to (d), the transformation of a spindle-type into a eutectic system with limited solid solution upon increasing mutual solubility of the two components in the solid state, causing the solvus to intersect the solidus and liquidus curves and invariant eutectic points to appear, between which the solidus becomes isothermal.

3.6 Limited Miscibility in Melt

Two alternative types of topological relationships between liquid immiscibility (binodal) and crystallization (liquidus) in a binary system are illustrated in Figure 6. In Figure 6a, the consolute temperature of the binodal curve is above the liquidus, so the binodal and liquidus curves intersect. In a binary isobaric system, the equilibrium of immiscible liquids L_1 and L_2 with a solid phase is invariant. Therefore, the immiscible liquids must be in equilibrium with one and the same solid (B in Figure 6a) so that the two intersection points of the binodal and solidus curves are at the same temperature. The binodal curve represents stable univariant two-liquid equilibrium above the liquidus, but its extension below the liquidus is metastable (dashed line in Figure 6a). Alternatively, the consolute temperature and the whole binodal curve may lie below the liquidus and thus refer to a metastable state (Figure 6b). In this case, the liquidus segment above the metastable binodal is usually flattened and exhibits a characteristic sigmoidal shape.

Many metal oxides have limited solubility in typical silicate, borate, and other glass-forming melts, and liquid miscibility gaps are common in glass-forming systems. Glassmaking is often affected by both stable and metastable immiscibility or phase separation as it is usually called in technological literature [4, 5]. When a homogeneous melt in the compositional region of metastable liquid immiscibility is rapidly cooled from superliquidus temperatures, it may not crystallize for kinetic reasons, but the undercooled liquid may unmix when it gets below the metastable continuation of the binodal. The resulting emulsion is usually very fine, often submicron, and

quenches to turbid, opalescent glass. Another way to achieve metastable unmixing is to anneal an initially homogeneous glass at temperatures above the glass transition but below the metastable binodal.

4 Ternary Diagrams

With the addition of one more component as an independent variable, T - x diagrams become three-dimensional. The conventional form of these diagrams is that of a trigonal prism whose base is the plane of barycentric compositional coordinates and vertical axis is the temperature scale (Figure 7a). In three dimensions, two-phase liquidus equilibria plot along curved liquidus planes; the assemblages of liquid and two solid phases are univariant and plot along three-dimensional curves; four-phase equilibria, such as ternary eutectic E_{ABC} in Figure 7, are plotted as points. For convenience, ternary diagrams are usually presented not in three-dimensional form but as projections of topological elements, planes, curves, and points, on the basal compositional plane (Figure 7b). As in topographic maps, elevations along the temperature axis are traced by isothermal lines, and down-temperature directions along univariant curves are commonly indicated by arrows.

With an increasing number of components, the basic types of phase equilibria remain the same, so ternary diagrams can be viewed as various combinations of topologic relationships outlined in Section 3. Ternary diagrams may comprise binary and ternary compounds, solid solutions, and liquid miscibility gaps. For example, a hypothetical isobaric ternary phase diagram in Figure 8

Figure 6 Effect of the extent of liquid unmixing on the topology of a binary eutectic system. (a) Stable unmixing above the liquidus, intersecting at L_2 the small liquidus branch of the B component limited by the L_1 - L_2 tie line, below which it extends metastably. (b) Metastable unmixing below the liquidus, which generally shows an inflexion point near the critical composition of the solvus.

Figure 7 Eutectic phase diagram of a ternary system A–B–C. (a) Three-dimensional representation: the cotectic lines beginning from the binary eutectics (E_{AB} , E_{AC} , E_{BC}) to converge at the lower temperature of the ternary eutectic (E_{ABC}). features congruently melting binary and ternary compounds BC and A_2BC_2 and incongruently melting compounds B_4C and A_2B_3C . There are four invariant ternary eutectic and three invariant ternary peritectic points corresponding to the following reactions:

Figure 8 Phase diagram of a hypothetical ternary system with congruently and incongruently melting binary and ternary compounds. See text for discussion.

Stably coexisting solids are connected in Figure 8 by *tie lines*. Notably, the compositions of compounds plot within the primary crystallization fields when melting is congruent, but in the primary crystallization fields of some other phases when it is incongruent.

5 Some Phase Diagrams for Glass-Forming Systems

5.1 The Determining Influence of Cation Size and Charge

Typical glass-forming melts are mixtures of molten oxides with strong chemical interactions and covalent or ionic bonds between metal cations and the oxyanion O^{2-} . Metal cations in glass-forming systems are traditionally classified in two major groups, namely, network formers and network modifiers (Chapters 2.1 and 2.4). Network formers are small, highly charged cations with coordination numbers not greater than 4 and strong covalent bonds to O^{2-} . Fourfold coordinated Si^{4+} is the most common and important network former, but the group of typical network formers in natural and technological glasses also includes P^{5+} , B^{3+} , Ge^{4+} , Sb^{3+} , and As^{3+} . Network-modifying cations have ionic radii greater than 87.2 pm [6] and coordination numbers equal to or higher than 5 [7]. The group comprises alkali and alkaline earth cations (excluding Li^+ , Be^{2+} , and Mg^{2+}), rare earth cations, Th^{4+} , and U^{4+} . Cations with ionic radii greater than that of Si^{4+} (26 pm) but smaller than 87.2 pm belong

to the intermediate, amphoteric group. According to spectroscopic studies, amphoteric cations have at least two coordination numbers. One coordination number is 4 and another one is usually 5 or 6. The most important amphoteric cation in natural and technological glasses is Al^{3+} , but the group also includes Li^+ , Be^{2+} , Mg^{2+} , Mn^{2+} , Zn^{2+} , Sc^{3+} , Ga^{3+} , Ti^{4+} , Zr^{4+} , Hf^{4+} , Nb^{5+} , Ta^{5+} , and some other high field strength cations.

This importance of ionic radii stems from the fact that, as a first approximation, bonding can be considered to be primarily ionic in oxide systems. Notwithstanding the aforementioned role of Si speciation, element mixing then is determined by similarities in electric charges and ionic radii. In purely oxide systems, oxygen is the sole anion present so only cation mixing needs to be dealt with. For the same nominal charges, Na^+ (116 pm), for instance, readily substitutes for K^+ (138 pm) and Mg^{2+} (72 pm) for Fe^{2+} (78 pm) or Ni^{2+} (69 pm) but less so for Ca^{2+} (100 pm). When the electrical charges differ, substitution is nonetheless possible provided that a *charge-compensating* cation is also exchanged, as illustrated by the well-known coupled substitutions of Na^+ and Al^{3+} for Si^{4+} .

A selection of phase diagrams will now illustrate the fundamental link between the ionic characteristics of the metals (the nominal charge Z , ionic radius r , and ionic potential Z/r) and the phase equilibria between their oxides in the processes of melting, crystallization and glass formation. These examples are limited to the simplest and the most widely used glass-forming systems for technology and research.

5.2 Silica–Metal Oxide Binaries

Binary systems of silica with alkali and alkaline earth oxides (Figure 9) share common topological features, which include the occurrence of stable or metastable liquid immiscibility at high silica content and eutectic-type relationships between multiple congruently and incongruently melting binary compounds at high concentrations of metal oxides. The stability of intermediate compounds and the size of liquid miscibility gap systematically change with the nominal charge Z and radius r of the metal cation, a feature indicating that interactions between the components are actually predominantly Coulombic in nature.

Regarding the stability of intermediate compounds, a general trend apparent in Figure 9 is that the composition of the most silica-rich compound shifts toward that of the metal oxide with increasing ionic potential Z/r of the metal cation. Whereas potassium tetrasilicate $\text{K}_2\text{Si}_4\text{O}_9$ with 80 mol % SiO_2 is stable in the K_2O – SiO_2 system, the most silica-rich compound in the other binary systems presented in Figure 9 are $\text{Na}_6\text{Si}_8\text{O}_{19}$ (73 mol % SiO_2), $\text{Li}_2\text{Si}_2\text{O}_5$

and $\text{Ba}_2\text{Si}_2\text{O}_5$ (67 mol % SiO_2), and CaSiO_3 and MgSiO_3 (50 mol % SiO_2). The stability of the silica-poor compounds with SiO_2 molar concentrations below 50 % also tends to increase with increasing Z/r .

The liquidus temperatures of the compounds are, however, more important for glassmaking than the compositions of intermediate compounds. Here the contrast between alkali and alkaline earth systems is dramatic, the liquidus temperatures being systematically lower for the former than for the latter. The differences are especially large at the lowest eutectic points, which are below 800 °C in K and Na binaries and above 1300 °C in alkaline earth systems. The low melting temperature of alkali silicates is one of the reasons why the first, most ancient artificial glasses were close to eutectic compositions in the Na_2O – SiO_2 system.

Liquid immiscibility is another major obstacle for glassmaking. Good correlation between the size of miscibility gaps in binary metal oxide–silica systems and Coulombic properties of the metal cations such as Z/r has been noticed ever since the pioneering studies by Greig [1]. To rationalize the correlation, Hess [17, 18] proposed that the forces responsible for melt unmixing at the atomic level are Coulombic and repulsive in nature. He pointed out that network-modifying cations are surrounded in silicate melts by both bridging and nonbridging oxyanions. Oxygen ions in bridging ($\text{Si}-\text{O}-\text{Si}$) and nonbridging positions ($\text{Si}-\text{O}-\text{M}$, where M is a network-modifying cation) isolate the network-modifying cations from one another by providing screens that mask the positive charges. However, modifier cations that are partly or wholly coordinated by bridging oxygen are poorly shielded from one another because the bridging oxygen ions are bonded to Si^{4+} cations by strong covalent bonds. Consequently, significant Coulombic repulsions build up between network-modifying cations, which may eventually result in phase separation through melt unmixing. The higher the ionic potential of modifier cations, the greater the Coulombic repulsions between them, and the larger the width of the resulting miscibility gap.

In a detailed analysis of binary systems, Hudon and Baker [7, 19, 20] noticed that the relationships between the ionic potential of network-modifying cations and the size of miscibility gaps are not linear. Furthermore, each group of homovalent cations (cations with the same Z) forms its own trend (Figure 10). For each group, the compositional width of miscibility gap and the unmixing temperature increase with Z/r reach a maximum and then decrease. The maximum is reached at $r = 87.2$ pm, which, as mentioned above, defines the transition from true network modifiers to amphoteric cations. Hudon and Baker assumed the existence of structural control on immiscibility in which the cation radius appears to have an important role. To rationalize the convex trends,

Figure 9 Phase equilibria in binary silica-metal oxide systems. Data for Li₂O [8], Na₂O [9, 10], K₂O [11], MgO [12], CaO [13, 14], and BaO [15]. Liquid miscibility gaps according to [7] and references therein. Source: Redrawn from [16], simplified.

Figure 10 Maxima in the critical temperatures of liquid miscibility in metal oxide–silica binaries when plotted against the ionic potential of the metal ion Z/r after [7]. Ionic radii r in nanometers [6]. Parabolic curves visually fitted to the points for homovalent cations.

they pointed out the increasing degree of covalency of the M–O bonds in homovalent groups of elements with decreasing r . Therefore, amphoteric cations capable of fourfold coordination seem to undergo weak or no Coulombic repulsion and tend to produce little or no phase separation.

Liquid miscibility gaps in complex multicomponent silicate melts tend to expand with additions of even small amounts of Fe, Ti, and P. The effects of Fe because of its high natural abundance are of special importance for immiscibility in natural magmatic melts. An anomalously low solubility of Fe ions in silicate melts appears to result from characteristic features of electron shells. Cations of transition elements from the first row in the periodic table, such as Fe^{2+} , Co^{2+} , Ni^{2+} , Cu^{2+} , V^{3+} , and Cr^{3+} , have five d-electron orbitals, which poorly shield atomic nuclei [7, 19]. Notably, miscibility gaps associated with the divalent cations in corresponding oxide–silica binaries are larger than expected from the general Z/r trend, and immiscibility gaps are even greater in binaries of trivalent Cr^{3+} , V^{3+} , and Fe^{3+} [7, 19].

5.3 The System Na_2O – CaO – SiO_2

Soda-lime silicates are of prime technological importance not only for the glass industry but also for the production of Na–Ca glass ceramics and Portland cement. The system comprises numerous binary and ternary compounds and invariant eutectic and peritectic points (Figure 11).

The compositions of the most common commercial glasses such as window and container glasses lie close to the ternary eutectic O at 725 °C (Figure 11) in the primary crystallization field of the ternary phase devitrite $\text{Na}_2\text{Ca}_3\text{Si}_6\text{O}_{16}$. As indicated by its name, this phase is the principal devitrification product of commercial soda-lime-silica glasses. It represents a typical example of an incongruently melting phase since it decomposes at 1060 °C into Ca metasilicate (CaSiO_3) and a 20 Na_2O •15 CaO •65 SiO_2 (wt %) liquid.

The consolute temperature of the liquid immiscibility dome, which is well above 1800 °C in the boundary system CaO – SiO_2 , rapidly decreases upon addition of Na_2O . The immiscibility dome eventually dives below the liquidus of silica polymorphs and becomes metastable at Na_2O concentrations of only 3 wt %. Metastable immiscibility extends to the compositions of commercial glasses for which evidence of phase separation has been found by electron microscope analyses of carefully etched samples [5].

5.4 Borosilicate Systems

Sodium borosilicate glasses are characterized by lower thermal expansion coefficients, better chemical durability, higher dielectric strengths, and higher softening temperatures than comparable soda-lime-silica glasses (Chapter 7.6). These advantages are reflected by the great variety of their consumer and technological applications. The ternary phase diagram Na_2O – B_2O_3 – SiO_2 (Figure 12) contains information fundamental for manufacturing of borosilicate glasses.

Although the limiting systems Na_2O – B_2O_3 and Na_2O – SiO_2 comprise numerous binary compounds, no ternary compound appears on the liquidus of the ternary system, in accordance with the lack of intermediate compounds in the B_2O_3 – SiO_2 system. The network formers B_2O_3 and SiO_2 have eutectic-type melting relationships, where the eutectic point strongly shifts toward the low-melting B_2O_3 . Binary mixtures of boron oxide and silica show strong tendency to metastable immiscibility in a broad compositional range below the liquidus of silica polymorphs. Compositions of commercial sodium borosilicate glasses lie in the silica primary crystallization field where liquidus temperatures drop below 1100 °C (Figure 12).

6 Perspectives

As a result of the systematic efforts made for more than a century, by far phase diagrams remain the most extensive source of thermodynamic information available for oxide

Figure 11 Phase diagram of the ternary system Na_2O – CaO – SiO_2 [21–24]; numbers are in mol %. Field of stable liquid immiscibility indicated as $L_1 + L_2$. materials. Hence, they constitute the main basis on which analyses are in turn performed to set up thermodynamic models with which not only phase equilibria but also oxide activities and other relevant parameters can be predicted for very wide compositional ranges (Chapter 5.3). Compared to phase equilibria experiments, calculations have of course tremendous advantages in terms of cost and rapidity, so efforts are actively pursued to improve their accuracy and reliability. It should be kept in mind, however, that most phase diagrams have been determined from optical observations of quenched samples at times when modern microanalytical methods (Chapter 2.2) were not existing. As a result, it is likely that many diagrams considered as eutectic would actually exhibit limited solid solutions, as has been shown in the important system $\text{SiO}_2\text{--CaAl}_2\text{Si}_2\text{O}_8$ by the presence of an excess SiO_2 in the anorthite structure [26]. Although it is unlikely that even the most important phase diagrams will be redetermined with the added benefit of microanalyses, such limitations of the available data should not be overlooked in current and future theoretical work.

Thermodynamic Models of Oxide Melts

Giulio Ottonello

Chair of Geochemistry, Laboratorio di Geochimica at DISTAV, University of Genoa, Genova, Italy

1 Introduction

When prepared by the usual melting process, glasses have of course melts as *precursors*. Their lack of long-range order then reflects that of the melt frozen in at the glass transition if the rate of heat loss on cooling is high enough with respect to the rate of the structural rearrangements that would lead to the crystalline phases. Although prediction of kinetic factors such as minimum cooling rates for vitrification is beyond the scope of equilibrium thermodynamics, thermodynamic models of melts are important for glass makers, metallurgists, and earth scientist. Because these models are devised to predict equilibrium conditions of melts with crystalline or vapor phases (Chapter 5.2), they may be used either to determine the appropriate melting conditions of glasses and slags or to reconstruct the history of igneous rocks. In this respect, temperature is not the only intensive parameter to be dealt with. The partial pressures of volatiles, redox conditions, and pressure (in earth sciences) have also to be considered as they can greatly affect phase equilibria or physical properties of glasses such as color (Chapter 6.2).

At a given temperature (T) and pressure (P), the equilibrium state of a system is determined by the minimum of its Gibbs free energy

$$G = H - TS, \quad (1)$$

where H is enthalpy and S entropy. A thermodynamic model thus relates the enthalpy and entropy of a system to its temperature, pressure (if needed), and composition (x) so as to make possible to find the minimum of G under the conditions of interest. Any thermodynamic model is in fact based on two different kinds of assumptions. The

first deals with the set of components in terms of which the chemical composition of the system is expressed, the second with the formal relationships with which the mole fractions of the selected components are mutually related in the used enthalpy and entropy expressions.

From the outset we will emphasize that a component (i.e. a “stoichiometric entity” represented by a group of atoms) on which is resting any phenomenological thermodynamic theory of mixed phases may be suggestive of certain structural features. But if such features represent a potential advantage, they are certainly not a foundation on which the theory rests. Moreover, a major problem encountered for oxide melts is that they are *associated liquids*, i.e. they have a complex structure that is continuously rearranged and in which the relevant molecular species are short lived and, thus, not readily identified. This is the reason why melt components have been defined in many different ways in the literature. The simple system $(\text{Mg}, \text{Fe})_2\text{SiO}_4$ (olivine in the crystalline state) may, for instance, be considered as composed of Fe_2SiO_4 (fayalite) and Mg_2SiO_4 (forsterite), of oxides (MgO ; FeO ; SiO_2), of elements (Mg ; Fe ; O), or of ions (Mg^{2+} , Fe^{2+} ; O^{2-}), the only requirement being that the number of components be consistent with the phase rule. Correlatively, analytical expressions used for G also show wide differences. As exemplified in silicates by the change from the three-dimensional network of SiO_4^{4-} tetrahedra of pure SiO_2 to the isolated SiO_4^{4-} units of SiO_2 -poor systems (Chapter 2.4), the structure of a melt can in addition change so much with composition that large differences can be found between the approaches followed by metallurgists interested in compositionally simple SiO_2 -poor slags and by glass scientists and geochemists focusing on complex SiO_2 -rich melts.

As a result, there is at this moment no single thermodynamic model with which phase equilibria can be calculated for any kind of oxide melts. Although it is clearly beyond

Reviewers: R. Conradt, RWTH Aachen University, Aachen, Germany
P. Papale, Istituto Nazionale di Geofisica e Vulcanologia, Pisa, Italy

the scope of this chapter to review the large diversity of models proposed in the literature, most of them can be grouped into one of the four classes that can be termed (i) fictive-chemical, (ii) fictive-structural, (iii) quasi-chemical, and (iv) polymeric. As it will be discussed here, the philosophy beyond each one of the four classes is basically different, so all models have their own advantages and drawbacks, with the consequence that their uses are generally restricted to specific ranges of composition under limited temperature and pressure intervals.

2 General Considerations

2.1 Gibbs Free Energy Minimization Principle and Mixing Properties

In depicting the mixing properties of a multicomponent liquid, it is convenient to adopt a *mixture* notation with which all components in mixture usually have as a standard state the pure component at the T and P of interest. In an ideal mixture there are no interactions between individual components, so the enthalpy of mixing (ΔH_{mix}) is zero. But mixing between n components in a mixture necessarily causes an increase of entropy. For ideal (i.e. random) mixing, this increase is given by

$$\Delta S_{\text{mix,id}} = -R \sum_{i=1}^n x_i \ln x_i, \quad (2)$$

where x_i is the mol fraction of the i th component. As a net result, the chemical potential of the i th component in the ideal mixture at P and T simply varies with composition according to

$$\mu_{i,P,T} = \mu_{i,P,T}^0 + RT \ln x_{i,P,T}, \quad (3)$$

where $\mu_{i,P,T}^0$ is the standard state potential at the P , T of interest. In condensed phases in general, and oxide crystals and melts in particular, mixing is not ideal because species interact more or less strongly and, as a consequence, are not randomly mixed. The relation with the standard state potential is then depicted in terms of the *thermodynamic activity* $a_{i,P,T}$:

$$\begin{aligned} \mu_{i,P,T} &= \mu_{i,P,T}^0 + RT \ln a_{i,P,T} = \mu_{i,P,T}^0 + RT \ln x_{i,P,T} \\ &\quad + RT \ln \gamma_{i,P,T}. \end{aligned} \quad (4)$$

where $\gamma_{i,P,T}$ is the activity coefficient.

The Gibbs free energy of the system is related to the chemical potential μ of the various components in the system and their number of moles n by

$$G_{(P,T,x)} = \sum_{i=1}^n n_i \mu_{i,P,T}. \quad (5)$$

With this definition, it follows from the Gibbs free energy minimization principle that another criterion for equilibrium in a multiphase system is that the chemical potential of any component be the same in all coexisting ($\alpha, \beta, \dots, \epsilon$) phases:

$$\mu_{i,P,T,\alpha} = \mu_{i,P,T,\beta} = \dots = \mu_{i,P,T,\epsilon}. \quad (6)$$

Finally, the temperatures at which crystal–liquid (or vapor–liquid) equilibria take place in solutions are not fixed. Thus, for each phase involved, the variations with temperature of the enthalpy and entropy terms must be calculated with the relevant heat capacity data. For example, at a given temperature T , the standard state enthalpy and entropy of the liquid and crystal components at T of reference (T_{ref}) are related by

$$H_{i,l}^0 = H_{i,c}^0 + \int_{T_{\text{ref}}}^{T_{\text{fus}}} C_{P,i,c} dT + H_{\text{fus}}^0 - \int_{T_{\text{ref}}}^{T_{\text{fus}}} C_{P,i,l} dT, \quad (7)$$

$$S_{i,l}^0 = S_{i,c}^0 + \int_{T_{\text{ref}}}^{T_{\text{fus}}} \frac{C_{P,i,c}}{T} dT + \frac{H_{\text{fus}}^0}{T_{\text{fus}}} - \int_{T_{\text{ref}}}^{T_{\text{fus}}} \frac{C_{P,i,l}}{T} dT, \quad (8)$$

where H_{fus}^0 is the enthalpy of fusion at the reversible temperature of fusion (T_{fus}) of the component. In other words, phase equilibrium calculations rely on extensive thermochemical information for all the phases considered. In this respect the enthalpies of fusion (or vaporization) and also the high-temperature heat capacities for the molten and crystalline (or vapor) phases are critical, especially when dealing with large freezing-point depressions that can attain, as in alkali-silica systems, more than 900 K. A summary of available data is found in Chapter 3.6.

Crystals in oxide systems are generally themselves solid mixtures. At least for minerals of geochemical interest, however, good thermodynamic models have already been set up and are thus ready to be used. In the case of melts, whereas there is no method to measure directly entropies of mixing, enthalpies of mixing can be determined calorimetrically. Unfortunately, these measurements are available for very few systems because they are time-consuming and beset by significant experimental uncertainties (Chapter 3.6).

It follows that the data employed to calibrate thermodynamic models of oxide melts are mainly experimentally determined phase diagrams. Most of them have been established between 1920 and 1960 from optical examination of samples quenched from given temperatures

and pressures. Although the liquidus and solidus temperatures bracketed in this manner are usually accurate to within a few degrees at room pressure, these determinations were made before the advent of chemical microanalyses, so crystals were assumed to be stoichiometric, and limited solid solutions could not be detected. Both assumptions introduce uncertainties in derived Gibbs free energies that should not be overlooked, although their evaluation is not easy.

2.2 A First Example: Melting in the CaO–SiO₂ System

As a real example, consider the equilibrium between a melt of a certain composition x along the *liquidus*, i.e. the P, T, x hypersurface separating the pure melt from the melt + crystal regions (Chapter 5.2). For this purpose we have selected the G – x relationship for the binary system CaO–SiO₂ at $P = 10^5$ Pa (i.e. 1 bar), first at $T = 1773.15$ K (hereafter noted as 1773 K) (Figure 1) and then in a wider temperature range (Figure 2). In addition to lime (CaO) and the β -quartz and β -cristobalite polymorphs of SiO₂, seven other compounds are found along the liquidus: hatrurite (Ca₃SiO₅), two polymorphs of Ca₂SiO₄ (α -larnite and bredigite), rankinite (Ca₃Si₂O₇),

Figure 1 Gibbs free energy of formation from the elements at the standard state of CaO–SiO₂ liquids (solid line) and of the precipitating crystal (symbols) on a 1 mol oxide basis (e.g. Ca₃SiO₅ $\Rightarrow$ Ca_{0.75}Si_{0.25}O_{1.25} etc.). Liquid computed with a hybrid polymeric approach [1, 2] adopting for the chemical interaction (G_{chem}) a T -dependent polymerization constant, $\ln K_p = -14939/T + 0.17$, and for the strain energy (G_{strain}) a subregular expansion operating on the SiO₂-rich side of the system, $f(x) = -1.2 \times (1 - 2x_{\text{SiO}_2}) - 8 \times (1 - 2x_{\text{SiO}_2})^6$; $x_{\text{SiO}_2} \geq 0.5$. The bulk Gibbs free energy of mixing is weighted with the number of contacts between oxygen quasi-species (see Eq. 44), i.e. $G_{\text{mixing}} = \frac{(O^-)}{2} \times [RT \ln K_p + f(x)]$. See Ref. [2] for the sources of thermodynamic data concerning the crystalline phases.

Figure 2 Room-pressure liquidus of the CaO–SiO₂ system derived from the hybrid polymeric approach (solid line) and from observations (symbols).

and two polymorphs of CaSiO₃ (α -wollastonite and β pseudo-wollastonite).

The Gibbs free energies of formation of all these stoichiometric crystals are known at the temperature and pressure of interest from thermochemical measurements. To these values we have superimposed in Figure 1 the Gibbs free energies of formation of the liquids under the same conditions based on a simple polymeric model [1, 2]. This Gibbs free energy curve is generally concave upward and almost touches the Gibbs free energy points of the various solids, pointing to complete miscibility over a wide compositional range except at high silica content where the flatness of the $G = f(x)$ curve indicates a limited liquid immiscibility domain.

Either by minimizing G or by applying the equilibrium criterion (6), one finds that pseudo-wollastonite, α -larnite, and β -cristobalite coexist stably with melts whose SiO₂ mol fractions are 0.45 and 0.56 and 0.40 and 0.625, respectively. Repeating this exercise at various temperatures to collect the points of stable coexistence, one builds a isobaric phase diagram, i.e. a so-called Schreinemaker's projection of chemical potentials onto the T, x space at constant P , which delineates the stability fields of the various phases (Figure 2). In agreement with experimental observations [3], the calculations indicate that pseudo-wollastonite melts congruently at 1550 °C and forms a thermal barrier because initial liquids with SiO₂ mol fractions higher and lower than 0.5 become progressively more SiO₂ rich and more SiO₂ poor, respectively, when crystallization proceeds.

A detailed first-principles computation of the Gibbs free energy of crystalline CaSiO₃ at 1773 K yields a bulk energy of ~ 1177 hartree per mol of oxides, corresponding

to $\sim 3.09 \times 10^6$ kJ/mol [1 hartree = $\hbar^2/(m_e a_0)$ with $\hbar$ = reduced Planck's constant, m_e = mass of electron at rest, and a_0 = Bohr radius]. On the other hand, the Gibbs free energy of formation from the elements at 1773 K and 1 bar are -981.3 and -981.7 kJ/mol for the α - and β -phases of CaSiO_3 , whereas that of the liquid is -981.0 kJ/mol (-922.2 kJ arising from the simple summation of the chemical potentials of the pure CaO and SiO_2 liquid components and -58.8 kJ arising from mixing contributions). The overall net ΔG between the crystalline and the liquid states is about 0.7 kJ/mol, which indicates that the influence of the aggregation state of CaSiO_3 on the bulk energy of the substance is only ~ 226 ppb. This simple calculation stresses how much the calculated topology of a phase diagram may be affected by slight errors in the input thermochemical data (or in the mixing model).

3 Thermodynamic Models

3.1 Fictive-Chemical Models: Regular Mixtures

The purpose of this class of models is not to yield even an approximate physical explanation of the observed mixing properties of the phases but, rather, to account for them empirically through simple polynomial expansions of the excess Gibbs free energies of mixing. It is in fact this lack of concern for fundamental aspects that makes these models so useful, especially for chemically complex systems where many binary interactions cancel out to a large extent.

To this class belongs the mixing models developed by Ghiorso and coworkers [7] for the composition range of natural magmas with the *ad hoc* components listed in Table 1, whose choice was dictated by simple convenience, i.e. by the possibility of deriving realistic thermodynamic data for melt constituents through either empirical procedures or univariant equilibria involving their crystalline counterparts. Because all components have the same standard state (pure melt at the T , P of interest) and the interaction parameters do not vary with temperature, the model may be ascribed to a regular mixture of the zeroth principle (complete configurational disorder):

$$G_{\text{melt},P,T} = \sum_i n_i \mu_i^0 + RT \sum_i n_i \ln x_i + \frac{1}{2} n_{\text{total}} \sum_i \sum_j W_{ij} x_i x_j. \quad (9)$$

The first step in the model is a normative calculation to establish the molar amounts of the various melt components (Table 1). With 15 such components, one should know 120 W_{ij} parameters to describe all binary interactions. But application of inverse methods to the plethora of petrogenetic observations in natural systems shows

Table 1 Melt components in the Ghiorso–Carmichael model and calculation of their mol fractions from those of the oxides [7].

$\text{Si}_4\text{O}_8 = 0.25 \times [\text{SiO}_2 - 0.5(\text{FeO} + \text{MnO} + \text{MgO} + \text{NiO} + \text{CoO} + \text{CaO}) - \text{Na}_2\text{O} - \text{K}_2\text{O}]$
$\text{Ti}_4\text{O}_8 = 0.25 \times \text{TiO}_2$
$\text{Al}_{16/3}\text{O}_8 = 0.375 \times \text{Al}_2\text{O}_3$
$\text{Fe}_{16/3}\text{O}_8 = 0.375 \times \text{Fe}_2\text{O}_3$
$\text{Cr}_{16/3}\text{O}_8 = 0.375 \times \text{Cr}_2\text{O}_3$
$\text{Fe}_4\text{Si}_2\text{O}_8 = 0.25 \times \text{FeO}$
$\text{Mn}_4\text{Si}_2\text{O}_8 = 0.25 \times \text{MnO}$
$\text{Mg}_4\text{Si}_2\text{O}_8 = 0.25 \times \text{MgO}$
$\text{Ni}_4\text{Si}_2\text{O}_8 = 0.25 \times \text{CoO}$
$\text{Ca}_4\text{Si}_2\text{O}_8 = 0.25 \times \text{CaO}$
$\text{Na}_{16/3}\text{Si}_8/3\text{O}_8 = 0.375 \times \text{Na}_2\text{O}$
$\text{K}_{16/3}\text{Si}_8/3\text{O}_8 = 0.375 \times \text{K}_2\text{O}$
$\text{P}_{16/5}\text{O}_8 = 0.625 \times \text{P}_2\text{O}_5$
$\text{Sr}_8\text{O}_8 = 0.125 \times \text{SrO}$
$\text{H}_2\text{O} = 1 \times \text{H}_2\text{O}$

that only 55 out of these 120 parameters turn out to have significant values, so the others can thus be set equal to zero. Finally, as in Ghiorso's model, the excess Gibbs free energy of mixing does not depend on pressure; the volume, compressibility, and thermal expansion of the melt are obviously regarded as linear combinations of the values of its components. This “*isometric*” condition is however not compulsory for this class of models. Non-zero excess volumes are in fact necessary when describing, for instance, the P – T saturation hypersurface of $\text{H}_2\text{O} + \text{CO}_2$ fluids in natural magmas [8].

A remarkable feature for the model is its ability to account for the miscibility gaps observed in magmas. The topology of the Gibbs free energy of the mixing surface depicted in a multicomponent space may be rather complex. A saddle-shaped conformation may, for instance, describe spinodal decomposition as illustrated in Figure 3 by the partial derivative of the Gibbs free energy of mixing with respect to the mol fraction of the Si_4O_8 component:

$$\begin{aligned} \left(\frac{\partial G_{\text{mixing,melt}}}{\partial x_{\text{Si}_4\text{O}_8,\text{melt}}} \right)_{P,T,X_j} &= RT \ln a_{\text{Si}_4\text{O}_8,P,T,\text{melt}} \\ &= 4 \left(\mu_{\text{SiO}_2,P,T,\text{melt}} - \mu_{\text{SiO}_2,\text{melt}}^0 \right), \end{aligned} \quad (10)$$

where $a_{\text{Si}_4\text{O}_8,P,T,\text{melt}}$ is the thermodynamic activity of the Si_4O_8 component in the melt at the T , P of interest. In the SiO_2 -rich side of the diagram, spinodal decomposition at 1700 K is seen in Figure 3 as points b and d, implying fields of metastable homogeneity.

Figure 3 Ghiorso–Carmichael model [7]. Partial derivative of Gibbs free energy of mixing of melt with respect to Si_4O_8 component plotted against molar amount of silica in melt. Enlarged area: spinodal field of critical immiscibility (spinodal decomposition). Points = experimental observations.

From its first appearance on, the model has been continuously revised and “user-friendly” computer freeware codes have been developed. Based on the pioneering work of Ghiorso et al. recent releases (e.g. [9]) consider in detail the effect of pressure up to 3 GPa through calibration procedures based on an extended petrological database.

3.2 Fictive-Chemical Models: Mechanical Mixtures

The “*constitutional model*” [10] may be considered lying half way between the *fictive-chemical* and the *fictive-structural* classes. Although developed on a strictly chemical framework (i.e. that of *constitutional relations*), it implicitly contains structure-oriented concepts, inasmuch as the relative concentrations of components for a given bulk composition reflect the coexistence of short-range-order structural entities termed *chemical structure* [11].

The model is essentially based on the operative assumption that the heat capacity gaps between glass and crystal ($\Delta C_{p,g-c}$) and liquid and crystal ($\Delta C_{p,l-c}$) are nearly identical (ΔC_p) and constant in a wide T range. From the equalities,

$$S_{\text{vit}} + \int_{T_g}^T \frac{\Delta C_{p,g-c}}{T} dT = S_{\text{fus}} - \int_T^{T_{\text{fus}}} \frac{\Delta C_{p,l-c}}{T} dT, \quad (11)$$

$$H_{\text{vit}} + \int_{T_g}^T \Delta C_{p,g-c} dT = H_{\text{fus}} - \int_T^{T_{\text{fus}}} \Delta C_{p,l-c} dT, \quad (12)$$

where S_{vit} and S_{fus} are the entropy of vitrification at the glass transition T_g and the entropy of fusion, respectively, and H_{vit} and H_{fus} their enthalpic counterparts, one thus gets for $T \gg T_g$:

$$S_{\text{vit}} - \Delta C_p \ln \frac{T_g}{T} \approx S_{\text{fus}} - \Delta C_p \ln \frac{T_{\text{fus}}}{T}, \quad (13)$$

$$H_{\text{vit}} + \Delta C_p (T - T_g) \approx H_{\text{fus}} - \Delta C_p (T_{\text{fus}} - T). \quad (14)$$

With the above provisos, one calculates the thermodynamic quantities of the glass and the liquid by assuming the fictive components (k) to be those of *mechanical mixtures* (i.e. $\Delta H_{\text{mix}} = \Delta S_{\text{mix}} = 0$):¹

$$H_{\text{glass}}^0 = \sum_k n_k (H_k^0 + H_{\text{vit},k}); \quad S_{\text{glass}}^0 = \sum_k n_k (S_k^0 + S_{\text{vit},k}), \quad (15)$$

$$H_{1673,\text{liq}}^0 = \sum_k n_k H_{1673,\text{liq},k}^0; \quad S_{1673,\text{liq},k}^0 = \sum_k n_k S_{1673,\text{liq},k}^0, \quad (16)$$

$$C_{p,\text{liq}} = \sum_k n_k C_{p,\text{liq},k}, \quad (17)$$

$$H_{T,\text{liq}} = H_{1673,\text{liq}}^0 + C_{p,\text{liq}} (T - 1673), \quad (18)$$

$$S_{T,\text{liq}} = S_{1673,\text{liq}}^0 + C_{p,\text{liq}} \ln \left(\frac{T}{1673} \right). \quad (19)$$

In these Eqs. H_{glass}^0 and S_{glass}^0 are the standard enthalpy and entropy of the *rigid* glass at 298 K, 10^5 Pa, respectively, whereas $H_{1673,\text{liq}}^0$ and $S_{1673,\text{liq}}^0$ are the enthalpy and entropy of the melt at 1673.15 K, and $H_{T,\text{liq}}$, $S_{T,\text{liq}}$, and $C_{p,\text{liq}}$ are the enthalpy, entropy, and heat capacity of the melt at the high temperature T [10, 11]. One then obtains the molar amounts (n_k) and masses (m_k) of the fictive components from a normative deconvolution of the bulk glass or liquid composition by applying

$$\vec{n}_j = (\nu_{jk}) \cdot \vec{n}_k \Rightarrow \vec{n}_k = (A_{kj}) \cdot \vec{n}_j, \quad (20.1)$$

¹ The Gibbs energy of a mixture of oxide components i reads $G = \sum n_j \cdot G_j^\circ + \Delta G_{\text{mix}}$; G_j° = Gibbs energy of pure component i ; $\Delta G_{\text{mix}} = \Delta H_{\text{mix}} - T \Delta S_{\text{mix}}$. If the constitutional compounds k (in their crystalline, glassy, or liquid state, respectively) are chosen instead as frame of description, then $\Delta H_{\text{mix}} \rightarrow \text{nil}$ (coexistence = absence of interaction; ideal mixing) and $\Delta S_{\text{mix}} \rightarrow \text{nil}$ (N atoms accumulated in one entity k) brings Eq. (2) into the form $\Delta S_{\text{mix,id}} = -(R/N) \cdot \sum n_k \ln x_k$. Thus, written in the frame of k , the Gibbs energy assumes the form of a “*mechanical*” mixture $G = \sum n_k \cdot G_k^\circ$ (R. Conradt, pers. comm.).

$$\vec{m}_j = (\omega_{jk}) \cdot \vec{m}_k \Rightarrow \vec{m}_k = (B_{kj}) \cdot \vec{m}_j, \quad (20.2)$$

$$(A_{kj}) = (\nu_{jk})^{-1}, (B_{kj}) = (\omega_{jk})^{-1}. \quad (20.3)$$

where ν_{jk} is the matrix element indicating how many mols of oxide j are present in the fictive component k , ω_{jk} states how many kg of oxide j are contained in 1 kg of component, and A_{kj} and B_{kj} are the elements of the inverted matrices (ν_{jk}) and (ω_{jk}) , respectively. The thermodynamic data for the fictive components employed to represent the crystalline reference systems (c.r.s.) of industrial glasses and liquids are listed in Table 2. The chemical fragmentation of the system and the fact that a good part of the ideal and excess mixing terms is embodied in the standard state values of the fictive components ensures a sufficient precision for industrial purposes since the integral thermodynamic properties of glasses and melts are predicted to within uncertainties lower than 5% [11].

3.3 Fictive-Structural or Cellular Models

This third class of models aims at representing the reactive properties of the species actually present in chemically complex melts by relying on an *a priori* choice of structural features, such as the existence of particularly stable complexes in the mixture, or fictive-structural units.

Let us consider again CaO–SiO₂ binary melts. In the cellular model one assumes that they contain three structural units, with a bridging oxygen linked either to two silicon atoms (Si–O–Si), to one silicon and one calcium atoms (Si–O–Ca), or to two calcium atoms (Ca–O–Ca). These structural units mutually react with an energy change that can be assimilated to that of a quasi-chemical reaction of the type

An interaction energy change $2W_{ij}$ is associated to reaction (21). This energy is not sufficient to describe all interaction effects in the liquid phase, so an additional term E_{ij} is necessary to account for those between the (Si–O–Si) and (Si–O–Ca) moieties. The Gibbs free energy of the mixture is then given in terms of partition function Q :

$$G_{\text{mixture}} = -RT \ln Q, \quad (22)$$

$$\ln Q = -\frac{E_0}{RT} + \ln g, \quad (23)$$

where E_0 is the energy of the (liquid) system in its stable configuration and g represents the configurational degeneracy of the system at E_0 . In the model assessment developed at IRSID [12], the interaction terms are expanded as a function of the molar fraction of the components to which the highest cationic charges are associated.

Although these adopted interaction terms do not depend on temperature, they dominate over the configurational effects. The resulting Gibbs free energy of mixing in the liquid phase is thus virtually unaffected by temperature. This peculiarity is common to other systems where silica is mixed with a strongly basic oxide (see Section 3.5) and has a deep intrinsic significance because the interaction is mostly dictated by the contrasting way in which the two oxides accept or donate oxygen ions in the sense of the Lux–Flood acid–base theory. For the CaO–SiO₂ system, good agreement is achieved by the cellular model in terms of six interaction parameters with, for instance, the experimentally observed activities of oxide components (Figure 4).

In the Shakhmatkin–Vedishcheva–Wright associated solution model developed for alkali-silicate and borate liquids and glasses [13–15], it is assumed that “*salt-like products*” or “*groupings*” [13] form between a generic metal oxide M_2O and the network formers within a restricted concentration range (0–50% M_2O) as described by the general reaction:

where i in the above equation is the stoichiometric amount of boron oxide (or silica) in the various groupings. It is assumed to correspond to what is observed in the crystalline compounds known to nucleate in the system of interest. The liquid (or glassy) mixture is assumed to be ideal, and the molar fractions of the various species are defined by [13]:

$$k_i = \frac{x_{M \cdot iB(\text{Si})}}{x_M \cdot x_B^i}, \quad (25)$$

$$x_M^* = \sum_i n_{M \cdot iB(\text{Si})} + n_M, \quad (26)$$

$$x_{B(\text{Si})}^* = \sum_i i \cdot n_{M \cdot iB(\text{Si})} + n_{B(\text{Si})}, \quad (27)$$

$$x_j = n_j / \left(\sum_i n_{M \cdot iB(\text{Si})} + n_M + n_{B(\text{Si})} \right). \quad (28)$$

where k_i is the equilibrium constant of reaction (24); $x_{M \cdot iB(\text{Si})}$, x_M , $x_{B(\text{Si})}$ are the mol fractions of the salt-like groupings and oxides, $n_{M \cdot iB(\text{Si})}$, n_M , $n_{B(\text{Si})}$ the molar amounts of the same species, and x_M^* , $x_{B(\text{Si})}^*$ the “*analytical*” composition of the investigated liquid or glass (i.e. $x_M^* + x_{B(\text{Si})}^* = 1$).

Assuming for simplicity that the equilibrium constants k_i in the liquid (or glass) are equal to those observed for the crystalline counterparts (and, as such, readily obtainable from the tabulated values of the Gibbs free energy of formation from the elements of the simple oxides and

Figure 4 Component activities in CaO-SiO₂ melts at 1823 K and 1 bar: predictions from the cellular model developed at IRSID (dashed lines) [12] and from the modified version of Taylor and Dinsdale (solid lines) [16] are compared with various experimental results at similar temperatures (open symbols).

their salts), the Gibbs free energy of formation of the liquid (or glass) of interest ΔG_f is obtained as

$$\Delta G_f = \sum_i n_i \Delta G_i^0 + RT \sum_j n_j \ln x_j \quad (29)$$

where the i summation is taken only over the salt-like groupings while that in j includes the unreacted oxides.

The application to alkali silicate and borate glasses reveals a remarkable model capability to reproduce the observed NMR experimental speciation [13–15] and other relevant structural data available in literature.

3.4 Quasi-Chemical Models

With quasi-chemical approaches, the energy involved in discrete interactions among quasi-species in solution is investigated in detail. Contrary to the previous ones, these models assign a precise structural meaning to these interactions.

Specifically [17], they assume that in a binary system with components 1 and 2, the 1 and 2 *particles* mix substitutionally in a quasi-lattice obeying a short-range ordering dictated by the equilibrium

$$[1-1] + [2-2] \rightleftharpoons 2[1-2], \quad (30)$$

with some analogy with Eq. (21). The molar enthalpy change associated with equilibrium (30) is expressed in terms of pairwise bond energies ε_{ij} :

$$\omega = \frac{Nz}{2} (2\varepsilon_{12} - \varepsilon_{11} - \varepsilon_{22}), \quad (31)$$

where N and z denote the number and coordination of the complex, respectively.

The nonconfigurational part of the molar entropy is also given in terms of bond contributions η_{ij} (nonconfigurational entropy of the ij pair bond):

$$\eta = \frac{Nz}{2} (2\eta_{12} - \eta_{11} - \eta_{22}). \quad (32)$$

We will denote by x_{ij} the mol fraction of the ij particle with respect to the total of the particles formed in the

system. Since each atom i is bonded to z_i neighbors, it follows from mass balance that

$$\frac{x_{12}}{2} = (x_1 - x_{11}) = (x_2 - x_{22}). \quad (33)$$

The enthalpy of mixing then becomes

$$H_{\text{mixing}} = \frac{x_{12}}{2} \omega. \quad (34)$$

The nonconfigurational (excess) entropy of mixing is

$$S_{\text{mixing,non-conf}} = \frac{x_{12}}{2} \eta, \quad (35)$$

and the configurational (ideal + excess) entropy of mixing is

$$S_{\text{mixing,conf}} = -R(x_1 \ln x_1 + x_2 \ln x_2) - \frac{Rz}{2} \left(x_{11} \ln \frac{x_{11}}{x_1^2} + x_{22} \ln \frac{x_{22}}{x_2^2} + x_{12} \ln \frac{x_{12}}{2x_1x_2} \right). \quad (36)$$

The equilibrium concentrations of the various pairs are determined by the minimum of the Gibbs free energy:

$$\frac{\partial G_{\text{mixing}}}{\partial x_{12}} = \frac{\partial (H_{\text{mixing}} - TS_{\text{mixing}})}{\partial x_{12}} = 0. \quad (37)$$

Through appropriate expansions in terms of Eqs. (34)–(36), one then obtains

$$\frac{x_{12}^2}{x_{11}x_{22}} = 4 \exp \left[\frac{-2(\omega - \eta T)}{zRT} \right]. \quad (38)$$

The name “*quasi-chemical*” assigned to the model stems from the fact that the right-hand term in Eq. (38) reduces to a constant for constant values of ω and η . This expression thus resembles a chemical reaction among ideal [1-1], [2-2] reactants and [1-2] product.

From Eq. (38) one gets [18]

$$\frac{x_{12}}{2} = \frac{2x_1x_2}{1 + \xi}, \quad (39)$$

where

$$\xi = \left\{ 1 + 4x_1x_2 \left[\exp \left(\frac{2(\omega - \eta T)}{zRT} \right) - 1 \right] \right\}^{1/2}. \quad (40)$$

Figure 5 Integral mixing properties for different values of the interaction parameter ω in the quasi-chemical model of binary SiO_2 -MO join: (a) enthalpy; (b) entropy.

The model is resolved first in terms of equilibrium distribution of particles with Eqs. (32) and (39) and (40) and then in terms of enthalpy and entropy with Eqs. (33) and (34) and (35), respectively.

The computed enthalpy and entropy terms have a typical V-shaped and M-shaped conformation; the more pronounced, the more negative the value assigned to ω . The quasi-chemical enthalpies and entropies of mixing computed with $z = 2$, $\eta = 0$ and various values of ω are shown for comparison in Figure 5 for a $\text{MO-Si}_{0.5}\text{O}$ system. When ω and η are set equal to zero, the mixture is obviously ideal, whereas the mixture is strictly regular when $\eta = 0$ and $x_{12} = 2 x_1 x_2$. In all cases the properties of the mixture are depicted however as asymmetric in the compositional space of interest.

The asymmetry about the intermediate composition has long been regarded as a severe limitation of the quasi-chemical model when applied to silicate melts (slags included), because it yields consistently maximum ordering about the composition $x_{\text{MO}} = 2/3$ in the MO-SiO_2 chemical space. To render symmetric the maximum ordering condition embodied by this model – i.e. to make it consistent with Eq. (2) – the true molar fractions x_1 , x_2 may be substituted with “equivalent fractions” y_1 , y_2 such that [18]

$$y_1 = \frac{b_1 x_1}{b_1 x_1 + b_2 x_2}; \quad (41.1)$$

$$y_2 = \frac{b_2 x_2}{b_1 x_1 + b_2 x_2}. \quad (41.2)$$

The coefficients b_1 and b_2 are chosen in such a way as to ensure $b_1/(b_1 + b_2) = 1/3$ and $b_2/(b_1 + b_2) = 2/3$. One readily sees that when $x_1 = 2/3$ and $x_2 = 1/3$, we have $y_1 = y_2 = 0.5$.

To assign more computational flexibility to the model, the ω and η parameters are finally expanded as polynomial functions of the equivalent fractions y_1 , y_2 , viz.

$$\omega = \omega_0 + \omega_1 y_2 + \omega_2 y_2^2 + \dots \omega_n y_2^n, \quad (42.1)$$

$$\eta = \eta_0 + \eta_1 y_2 + \eta_2 y_2^2 + \dots \eta_n y_2^n. \quad (42.2)$$

Extension to a ternary system, $\text{AO}_x - \text{BO}_y - \text{CO}_z$ (A–B–C hereafter) system is not straightforward because it involves the adoption of ternary interaction parameters, which may be obtained only by inverse modeling operating on the topology of the liquidus hypersurface. The Pelton–Blander modified quasi-chemical model is at the core of the FactSage commercial package (www.factsage.com), widely used in metallurgy and in the glass industry. Its precision in reproducing the experiments is remarkable thanks to the flexibility of the computational approach. As an example, the liquidus projection (univariant cotectics and invariant points) of the $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2$ system (CAS) is shown in Figure 6 as resolved by the FACT program. The phase relations in a binary system (i.e. a *Simplex* of degree 1) are readily represented graphically to indicate the equilibrium temperature of a given composition along the liquidus curve (Figure 2). For a ternary system (i.e. a *Simplex* of degree 2), however, the temperature information is necessarily lost in a 2-D plot so that isotherms are usually superimposed on the univariant liquidus hypersurfaces to depict their 3-D nature.

3.5 Polymeric Approach

In polymeric models, one postulates that, for each composition at given values of P and T , the melt is characterized by an equilibrium distribution of ionic species of

Figure 6 Solid–liquid equilibria calculated for the CaO–Al₂O₃–SiO₂ system with the FACT commercial package (<http://www.factsage.com>).

oxygen, metal cations, and ionic polymers of monomeric units SiO_4^{4-} . The charge balance of a polymerization reaction involving SiO_4^{4-} monomers may be formally described by a homogeneous reaction involving three forms of oxygen [19]: singly bonded O^- , doubly bonded (or *bridging oxygen*) O^0 , and free oxygen ions O^{2-} :

In fact, Eq. (43) is similar to a reaction between SiO_4^{4-} monomers:

A fundamental principle of polymer chemistry is that the reactivity is independent of the effective length of the polymer chains (cf. Chapter 8.8). It then follows [20] that this principle applies to the equilibrium constant of Eq. (43), which is

$$K_{43} = \frac{(\text{O}^0)(\text{O}^{2-})}{(\text{O}^-)^2}, \quad (45)$$

where the terms in parentheses represent the number of moles per unit mole of melt.

In a binary system MO–SiO₂, in which MO is the oxide of a completely dissociated basic cation, the total number of bonds per mole of melt is given by [21]

$$2(\text{O}^0) + (\text{O}^-) = 4N_{\text{SiO}_2}, \quad (46)$$

where N_{SiO_2} is the mol fraction of SiO₂. The number of bridging oxygens is thus

$$(\text{O}^0) = \frac{4N_{\text{SiO}_2} - (\text{O}^-)}{2}. \quad (47)$$

Mass balance gives the number of moles of free oxygen per mole of melt:

$$(\text{O}^{2-}) = (1 - N_{\text{SiO}_2}) - \frac{(\text{O}^-)}{2}, \quad (48)$$

where $(1 - N_{\text{SiO}_2})$ are the number of moles of the basic oxide. Then, Eqs. (46)–(48) yield

$$K_{43} = \frac{[4N_{\text{SiO}_2} - (\text{O}^-)][2 - 2N_{\text{SiO}_2} - (\text{O}^-)]}{4(\text{O}^-)^2}. \quad (49)$$

Finally (O^-) is given by the quadratic equation

$$(O^-)^2(4K_{43} - 1) + (O^-)(2 + 2N_{SiO_2}) + 8N_{SiO_2}(N_{SiO_2} - 1) = 0, \quad (50)$$

which may be solved for discrete values of K_{43} and N_{SiO_2} .

The symmetry problems encountered with the quasi-chemical model are *a priori* discarded because the ideal mixing terms are implicitly part of the bulk Gibbs free energy of mixing contribution, weighted in terms of $(O^-)/2$ contacts:

$$G_{\text{mixing}} = \frac{(O^-)}{2} RT \ln K_{43}. \quad (51)$$

The chemical interactions within the anion matrix of a n -component system are completely fixed by the interaction properties observed along the $n - 1$ limiting binaries [1, 22]. Denoting by $K_{P,A-F}$, $K_{P,B-F}$ the polymerization constants valid along the limiting A-F and B-F binaries, the polymerization constant of the extended Toop-Samis model turns out to be

$$\ln K_P = N'_{A^{v+}} + \ln K_{P,A-F} + N'_{B^{v+}} + \ln K_{P,B-F} + \dots \quad (52)$$

For a compositionally complex melt, the above equation states that network-modifier cations A, B of charge ν_A^+ , ν_B^+ interact with free oxygen O^{2-} (and hence with

the polymeric units built up by the network former F) according to a simple proportionality described in terms of $N'_{A^{v+}}$, $N'_{B^{v+}}$ “electrically equivalent fractions” [22, 23]:

$$N'_{A^{v+}} = \frac{\nu_A^+ n_A}{\nu_A^+ n_A + \nu_B^+ n_B + \dots} \quad (53)$$

In light of this fact, it is possible to depict the thermodynamic properties of an n -component system through Toop’s asymmetric deconvolution (i.e. with the assumption that the cation matrix is not appreciably affected by anions while the anion matrix is affected by cations). As an example, the phase diagram of the CAS system calculated with the hybrid polymeric approach [1, 2] is shown in Figure 7. The 3-D representation emphasizes the role of temperature in conforming the liquidus. The porcelain rendering adopted to stress the importance of this system in ceramurgy should not be overlooked. The complex liquidus hypersurface was indeed obtained through convex-hull techniques [24] applied to a simplicial mesh (i.e. a mesh made up of the simplest polytypes) of 2×10^6 energy points for each temperature investigated.

4 First-Principles Calculations

Describing the application of first-principles methods to phase-equilibrium calculations is clearly beyond the

Figure 7 Solid-liquid equilibria calculated for the CaO-Al₂O₃-SiO₂ system with the hybrid polymeric approach [2]. The liquidus hypersurface was resolved through convex-hull techniques on a simplicial mesh of $100 \times 100 \times 100$ energy points for each temperature at 1 K scale discretization in the range 1000–3000 K. The surface was then smoothed, and a porcelain-like rendering of the diagram was selected to emphasize the importance of this system in ceramurgy.

scope of this chapter. Referring to Chapter 2.10 for a brief summary of their fundamental features, we will simply illustrate how results currently obtained indicate that the empirical coefficients of thermodynamic models will be soon substituted with energy terms arising from quantum-mechanical assessments. Of special interest in this respect is the recent finding [25] that polarizable ionic liquids such as silicate melts may be treated within the framework of the polarized continuum model (PCM) of Tomasi and coworkers [26].

The solvent parameters of silicate liquids treated as polarized continua in the framework of the Pierotti–Reiss scaled particle theory, coupled with the PCM, have in fact already been resolved on the basis of the plethora of high-temperature solubility experiments on inert gases [25]. In particular, silicate melts behave as ionic liquids of medium polarizability with dielectric properties intermediate between water and benzene whose effective solvent electrostatic radii (r_e) may be readily obtained with a scalar operation based on the collisional radius of Eyring (r_{coll}) [27]:

$$r_e = 1.138 \times r_{\text{coll}} - 0.3836 \text{ (Å)}. \quad (54)$$

A first application to the H_2O – SiO_2 system [28] has revealed that the solubility of molecular water in molten silica is indeed more complex than thought, being favored at low $X_{\text{H}_2\text{O}}$ content in the liquid by hydrogen bonding between molecular water (OH_2) and the hydroxyl terminations (OH°) replacing singly bonded oxygens (O°) on the terminations of polymer chains. The results of detailed calculations are listed in Table 3 carried out

for discrete compositions along the wet solidus of the H_2O – SiO_2 system and for the limiting compositions (i.e. pure H_2O at $T = 25^\circ\text{C}$, $P = 1$ bar and pure silica liquid at $T = 1723^\circ\text{C}$, $P = 1$ bar). The dramatic increase of Henry's law constant with temperature (last two rows) is due to the essentially entropic nature of the cavitation energy. Also note how intense are the (electrostatic + dispersive + repulsive) solute–solvent interactions (computed at the B3LYP/6-31 + $G(d, p)$ theory level within the framework of PCM and here collected in a comprehensive interaction term).

5 Perspectives

The variety of conceptual models hitherto proposed by metallurgists, ceramists, and geochemists may seem disconcerting because most of them are valid only over a limited part of the n -component systems of interest to their fields. In addition, the wealth of experimental information available that range from petrological phase diagrams and gas-phase equilibration studies to electrochemical galvanic-cell and calorimetric measurement and structural investigations, which should be taken into account, represent a formidable challenge and could lead to a pessimistic view about the possibility of a unifying approach to melt energetics. The giant steps achieved by computer science in terms of calculation speed and memory storage capabilities of parallel devices, however, now render feasible first-principles investigation of medium- and long-range disordered substances.

Table 3 Scaling particle theory energy terms [28]. The cavitation enthalpy at P of interest and T of reference ($H_{\text{cav},P,\text{Tr}}$), the interaction energy ($H_{\text{int},P,\text{Tr}}$ assumed as purely enthalpic), and the cavitation Gibbs free energies ($G_{\text{cav},P,\text{Tr}}$; $G_{\text{cav},P,T}$) are in kJ/mol. The cavitation entropy ($S_{\text{cav},P,\text{Tr}}$) is in J/(mol K). Volume terms are in cc/mol. $K_{P,\text{Tr}}$ and $K_{P,T}$ are the Henry's Law constants for H_2O in pure silica liquid at T_r , P_r of reference ($T_r = 298.15$ K; $P_r = 10^5$ Pa) and T , P of interest, respectively.

Figure 8 The σ -bonding orbitals of the $[\text{Si}_4(\text{OH}_2)_4]$ ring resolved at the B3LYP/TZVP theory level. The isodensity limit is $0.03 \text{ e}/\text{\AA}^3$ for both structures, the eigenvalue of the four-membered ring is -1.019 hartree, and that of the six-membered ring is -1.016 hartree. The electron clouds occupy essentially the xy plane in a standard arrangement [29].

That first-principles calculations reproduce experimental observations in heterogeneous P, T, x ranges makes us optimistic about the impact that full quantum chemistry applications will soon have for this class of substances. The road toward this goal is nevertheless still long and complex as new discoveries might render the target more distant than previously thought. We may quote in this respect the recent findings about the existence of the Pauling double bond between oxygen donor centers in silicate and silico-aluminate rings in the liquid [29]. Approaching cationic centers to the oxygen donors of the ring (z -axis in Figure 8), one observes a stabilizing effect in terms of orbital energy of the low-lying σ -bonding and antibonding molecular orbitals (MOs). Moreover, a detailed electron localization/delocalization analysis reveal an enhanced electron delocalization among O atoms, which is manifested in the Pauling's double bond nature of the bent σ -bonding MO between nonadjacent oxygen centers. This complex phenomenon acts in the direction opposite to what is commonly assumed with the statement that a basic oxide favors melt depolymerization by freeing oxygen donors. Even though new concepts may add further complexities, we confidently expect that further theoretical work will give a sounder basis to thermodynamic models and make them applicable to wider composition, temperature, and pressure ranges. In view of their complexity and of the very long computing times required for large systems, however, it is unlikely that such first-principles calculations will make, in a near future, the models described in this chapter obsolete for routinely predictions on phase equilibria.

1 Introduction

When any liquid is cooled below its equilibrium melting or *liquidus* temperature, one or several crystalline phases may form. This process takes place in two steps: the formation of clusters and their subsequent evolution to macroscopic crystals. The first step is denoted *nucleation*, and the second is *crystal growth*. The effect of simultaneous crystal nucleation and growth is denominated *crystallization*. Crystallization counteracts vitrification, the freezing of a melt into a glass. Upon heating, the same phenomenon results in glass devitrification.

Eight decades ago, G.W. Morey [1] stated that “Devitrification is the chief factor which limits the composition range of practical glasses, it is an ever-present danger in all glass manufacture and working, and takes place promptly with any error in composition or technique.” The prevention of crystal nucleation and growth upon cooling of any liquid – or upon heating of gels – gives rise to a glass. On the other hand, the global acceleration of technological breakthroughs, marked by high-tech industrial processes and devices, requires materials with unusual microstructures and enhanced or novel properties, such as transparency, bioactivity, ionic conductivity, or machinability, sometimes combined with excellent dielectric, magnetic, chemical, mechanical, or thermal shock resistance.

To meet this demand, significant efforts have focused on the synthesis of new glasses and glass ceramics. In both cases, crystallization control plays such a decisive role that

reliable models of crystallization processes are needed. Hence, knowledge about the possible pathways of crystallization allows one to formulate kinetic criteria to answer the questions: “Under what conditions can a liquid supercool and transform into a glass, and under what conditions is substantial crystallization expected to occur on the cooling path?” In attempts to produce new glasses, crystal nucleation and growth must be avoided. Conversely, controlled crystallization can be used to synthesize fully crystallized materials or semicrystalline glass ceramics (Chapter 7.11). Several monographs provide detailed information on these materials (e.g. [2, 3]).

However, these technological aspects represent only one side of the widespread scientific interest in the kinetics of nucleation and crystallization in glasses. In addition to their practical relevance, glass-forming liquids serve as remarkable experimental models of metastable, highly viscous systems, in which crystallization and liquid–liquid phase separation processes can be quickly initiated, accelerated, or delayed. These processes can thus be studied conveniently under very different conditions on a laboratory timescale. Such analyses may even include the dependence of the kinetics of phase formation on the thermal history of the sample. For this reason, glass-forming liquids have served as *guinea pigs* for testing crystal nucleation and growth theories, providing a deeper insight into different phase formation processes. And lastly, crystallization produces impressive, uniquely beautiful (and frequently hidden) nano- and microstructures, as demonstrated by E.D. Zanotto [4], which serves as an additional motivation to join and pursue research in this endless, albeit highly gratifying quest to unveil the deeply hidden intricacies of glass crystallization and the resulting properties of glass ceramics.

To prevent or induce controlled crystal nucleation and growth in a glass requires some theoretical understanding of these complex phenomena. This chapter, therefore, outlines the basic fundamental aspects of the theory of crystallization of supercooled inorganic glass-forming liquids. Section 2 begins with a description of crystal nucleation kinetics, followed in Section 3 by an overview of some basic modes of crystal growth. Section 4 describes overall crystallization kinetics, i.e. the evolution of the volume fraction of crystalline phases as a function of time by nucleation and growth. In addition to some well-established results, we also briefly discuss some open problems and possible approaches to their resolution. A summary of relevant results and perspectives for future developments (Section 5) completes this chapter.

2 Crystal Nucleation and Classical Nucleation Theory

The physical nature of nucleation phenomena in general and crystal nucleation in supercooled liquids in particular was first established and described by J.W. Gibbs [5]. His basic idea can be illustrated by the following approximation for the change of Gibbs free energy, ΔG , during crystal cluster formation:

$$\Delta G = -n \Delta\mu + \sigma A, \Delta\mu = \mu_l - \mu_{cr}, A = 4\pi R^2, n = \frac{4\pi}{3} c_\alpha R^3. \quad (1)$$

In formulating Eq. (1), it is assumed that spherical crystalline nuclei form in an initially homogeneous liquid. These nuclei are described by their radius, R ; surface area, A ; and the number, n , of particles (atoms, molecules, or more generally the basic structural units of the crystalline phase) they contain. In Eq. (1), $\Delta\mu$ is the difference of the chemical potentials per particle in the liquid (μ_l) and the crystal (μ_{cr}), σ is the specific interfacial energy, and c_α is the particle number density in the crystal cluster. From the specification of the parameters, it is evident that Eq. (1) is valid only for the simplest case of crystallization when liquid and crystal consist of the same structural units. This kind of crystallization is denoted as *congruent*. Also, it is assumed here that the state of the crystal clusters is independent of their sizes. Qualitatively, the situation does not change in general cases of *incongruent* crystallization, when the crystal and liquid phases have different compositions.

According to thermodynamic evolution criteria, at constant pressure, P , and temperature, T , spontaneous macroscopic processes are tied to a decrease in the Gibbs free energy, G , of the system. For this reason, if $\mu_l < \mu_{cr}$ and $\Delta\mu = (\mu_l - \mu_{cr}) < 0$, ΔG in Eq. (1) is a monotonically increasing

function of cluster size for any possible values of R , so that crystal clusters of any size will disappear over time. The function $\Delta G = \Delta G(R)$ takes on the shape shown in Figure 1a only if the thermodynamic driving force for crystallization, $\Delta\mu$, is positive ($\mu_{cr} < \mu_l$). In this case, cluster formation and growth are accompanied by a decrease in the Gibbs free energy if the surface term in the expression for ΔG is neglected. However, this tendency for decreasing Gibbs free energy is counteracted by the surface term, i.e. the surface contribution to Gibbs free energy initially leads to an increase in ΔG with increasing crystal size. Small crystal clusters formed in the system disappear, and only clusters larger than a critical size, R_c , can grow to macroscopic dimensions. As demonstrated in Figure 1a, the critical cluster size is defined by the maximum of $\Delta G(R)$. Systems showing such behavior are denoted as metastable. Metastable states are stable with respect to small fluctuations (generating clusters with sizes $R < R_c$) but unstable with respect to larger fluctuations (leading to clusters with sizes $R > R_c$). Thus, viable (supercritical) crystal clusters capable of deterministic growth must exceed a critical size. It is this criticality that determines the crucial impact of these embryos of the newly evolving phase on the nucleation processes.

Taking the chemical potential difference and the specific interfacial energy as constants (i.e. employing the so-called “capillarity” approximation), one can derive the critical cluster size and the value of ΔG_c at the critical size from the extremum condition $d(\Delta G)/dR = 0$. These parameters are given by

$$R_c = \frac{2\sigma}{c_\alpha \Delta\mu}, \Delta G_c = \frac{1}{3} \sigma A_c = \frac{16\pi}{3} \frac{\sigma^3}{(c_\alpha \Delta\mu)^2}, A_c = 4\pi R_c^2. \quad (2)$$

These relations remain valid if more accurate expressions for $\Delta\mu$ are employed and the curvature dependence of the interfacial energy is accounted for. The concepts discussed above are illustrated in Figure 1a within the framework of the classical model of nucleation, whereby the change in the Gibbs free energy of cluster formation reaches a maximum $\Delta G = \Delta G_c$ for the critical cluster size, $R = R_c$. In this model, the clusters grow or decay while preserving their properties, so size is the only parameter specifying the state of the cluster.

A more realistic picture of cluster formation is presented in Figure 1b, where not only the size but also the composition (described by the number of particles, n_i , of two components) of the cluster may change. In this case, the critical cluster corresponds to a saddle point of the Gibbs free energy surface. The evolution to the new phase via the saddle is shown by the dark (red in the colored version) curve. In Figure 1c, we show an alternative

Figure 1 The classical model of nucleation and possible generalizations. (a) With only one parameter employed to describe the state of the cluster. (b) Change of Gibbs free energy in cluster formation when more than one parameter is used. (c) Alternative to the classical scenario of crystallization in multicomponent liquids (See electronic version for color figures).

to the classical picture of phase evolution, which is similar to spinodal decomposition (cf. [3]). In this case, the composition of the critical crystal cluster changes retaining a nearly constant size and only after completion of this process the kinetics are governed by the growth of clusters with a roughly constant composition. In a variety of cases in multicomponent systems [3], the latter path of evolution (Figure 1c) – and not the classical picture (Figure 1a) – dominates phase formation.

Critical clusters do not form according to the predictions (the evolution criteria) of macroscopic thermodynamics, but instead by stochastic thermal fluctuations. According to underlying assumptions of statistical physics, the probability of such fluctuations can be expressed as a function of the minimum work for a reversible thermodynamic process. The minimum work to form a critical cluster is $W_c = \Delta G_c$, where ΔG_c is given by Eq. (2). This quantity, W_c , the work of critical cluster formation, plays a decisive role in nucleation theory. Initially, the nucleation rate is small. Then, after a certain time interval, τ , the so-called time lag for nucleation,

the rate of nucleation, J (i.e. the number of supercritical clusters formed per unit time in a unit volume of the liquid), approaches a constant value, the steady-state nucleation rate, J_s . In an early description of this initial period of nucleation by Zeldovich (cf. [3]), the nucleation rate as a function of time, t , was expressed by the relation

$$J(t) = J_s \exp\left(-\frac{\tau}{t}\right). \quad (3)$$

The initial stage of nucleation observed in experiments is often described by the Collins–Kashchiev relation (cf. [3]):

$$N(t) = J_s \tau \left[\frac{t}{\tau} - \frac{\pi^2}{6} - 2 \sum_{m=1}^{\infty} \frac{(-1)^m}{m^2} \exp\left(-m^2 \frac{t}{\tau}\right) \right]. \quad (4)$$

This mathematical equation gives a relation for the number, $N(t)$, of supercritical crystallites as a function on time, t . For longer times than some induction time ($t \gg t_{\text{ind}}$), Eq. (4) can be approximated by

Figure 2 Experimental nucleation rate data for several silicate glasses. (a) Reduced crystal number density, $(N(t)/J_s\tau)$, versus reduced nucleation time, (t/τ) . The solid line is the master curve calculated from Eq. (4). (b) Reduced nucleation rate versus reduced nucleation time calculated from Eq. (4). (c) Experimental steady-state nucleation rate, J_s , versus reduced temperature, T/T_m , for four stoichiometric glasses. T_m is the melting temperature (see [6] for details).

$$N(t) \cong J_s(t - t_{\text{ind}}), \quad t_{\text{ind}} = \frac{\pi^2}{6} \tau. \quad (5)$$

where τ is the nucleation time lag. Over a sufficiently large timescale, Eqs. (3)–(5) approach steady-state nucleation conditions, i.e. $(dN/dt) = J_s = \text{constant}$. With $W_c = \Delta G_c$, the steady-state nucleation rate, J_s , can be written as [3]

$$J_s = J_0 \exp\left(-\frac{\Delta G_c}{k_B T}\right) = J_0 \exp\left(-\frac{W_c}{k_B T}\right), \quad J_0 = \sqrt{\frac{\sigma}{k_B T}} \left(\frac{D}{d_0^4}\right), \quad (6)$$

where D is an appropriately chosen diffusion coefficient and d_0 is a size parameter explained in greater detail below. Experimental results that illustrate the establishment of a steady-state nucleation rate and its dependence on temperature are shown in Figure 2.

For the case shown in Figure 1a (congruent crystallization, assuming that the state of the cluster does not change with size and is the same as that of the newly evolving macroscopic phase), D in Eq. (6) is the diffusion coefficient of the structural building units in the liquid, and d_0 is their diameter. If several components of the liquid diffuse independently, D must be replaced by an effective diffusion coefficient, which is a combination of the partial diffusion coefficients and the concentrations of the different components in the liquid, and d_0 must be replaced by the average size of these independently moving species [3].

In the application of the theory, it is also often assumed that the effective diffusion coefficient can be replaced by

the Newtonian shear viscosity, η , via the Stokes–Einstein–Eyring (SEE) equation [3]:

$$D \cong \frac{k_B T}{d_0 \eta}. \quad (7)$$

However, its applicability to states near and below the glass transition temperature (where homogeneous crystal nucleation is commonly observable) has been questioned even for “one-component” congruent systems, where decoupling of relaxation (expressed by viscosity) and atomic transport (represented by the diffusion coefficient) is frequently reported (e.g. [7]). Application of this expression is even more questionable for multicomponent systems. Another issue is related to the case of highly viscous glass-forming melts, for which a non-Newtonian viscosity should be employed to describe viscous flow [3]. Leaving aside the reservations above, by applying the SEE relationship, one arrives at the following expression for the steady-state nucleation rate:

$$J_s = \frac{\sqrt{\sigma k_B T}}{d_0^5 \eta} \exp\left(-\frac{\Delta G_c}{k_B T}\right). \quad (8)$$

To apply Eq. (8) to the interpretation of experimental data, one has to determine the work of critical cluster formation, $W_c = \Delta G_c$, i.e. to specify the thermodynamic driving force of phase formation, $\Delta\mu$, and the specific interfacial energy, σ in Eq. (2). Assuming that the bulk properties of the crystal clusters are the same as those of the macroscopic crystals, one arrives at the simplest

approximation by a Taylor expansion of $\Delta\mu(T)$ in the vicinity of the melting temperature:

$$\Delta\mu(T) = \Delta h_m \left(1 - \frac{T}{T_m} \right), \quad (9)$$

where Δh_m is the enthalpy of melting per structural unit of the crystal and T_m is the melting temperature (generalizations of this relation can be found in [3]).

Since the interfacial energy of the critical nucleus is not directly measurable, it is normally evaluated using the Stefan–Skapski–Turnbull rule [3]:

$$\sigma = \zeta \frac{q_m}{N_A^{1/3} \nu_m^{2/3}}, \quad q_m = N_A \Delta h_m, \quad (10)$$

via the molar enthalpy of melting, q_m . In Eq. (10), N_A is Avogadro's number, ζ is a factor varying from 0.4 to 0.6, and ν_m is the molar volume. This relation has been widely employed (see [3] and Baidakov et al. [8]). By substituting these relations into the expression for the steady-state nucleation rate, its temperature dependence can be interpreted straightforwardly. The steady-state nucleation rate J_s is equal to zero at $T = T_m$, where $\Delta\mu = 0$, cf. Eq. (9). This rate increases with decreasing temperature because of the decrease in the work of critical cluster formation borne out by Eq. (2), until this trend is overcompensated by the exponential increase in viscosity with decreasing temperature.

When these classical concepts are employed to interpret experimental data, a qualitative and partly quantitative agreement is sometimes found (cf. Figure 2). In most cases, however, the classical approach underestimates the steady-state nucleation rates by 20–55 orders of magnitude, e.g. [6]. In the classical approach, the deviations between experiment and theory can be (artificially) resolved by the introduction of a size dependence of the specific interfacial energy, as discussed by Gibbs [5] and later by others, particularly by Tolman (cf. [3]). But this type of solution gives rise to other problems [6]. Another possible solution, in agreement with results of computer simulations and density functional computations, consists in accounting for the size dependence not only of the surface but also of the bulk properties of the clusters of the newly evolving phases. The bulk properties of the clusters generally depend on their sizes. Hence, the surface properties, including the surface tension, must also be size dependent. Thus, this approach also leads to a size dependence of the surface energy, but the primary variation of the properties of the clusters lies in the size dependence of their bulk properties.

Thermodynamically, one can treat these problems by generalizing the classical Gibbs approach (cf. [3]), which allows for a description of the cluster properties as a

function of size and degree of supercooling. With this new thermodynamic (generalized Gibbs) approach, one concludes that the classical theory – assuming macroscopic bulk properties of the clusters and employing the capillarity approximation for the specific interfacial energy – overestimates the work of critical cluster formation, and hence, underestimates the values of steady-state nucleation rates [3]. Therefore, the classical theory with the “capillarity” approximation may serve as a tool for roughly estimating the nucleation rate curve (i.e. its dependence on temperature and/or pressure), but it must be improved to account for the above-specified effects for a detailed and quantitatively accurate description of the phenomenon.

So far, we have considered the case of crystal nuclei that form evenly within a pure liquid. This mechanism is known as *homogeneous* nucleation. However, nucleation can be readily catalyzed by impurities, such as solid particles embedded in the volume or present on the external surface of glasses. Nucleation originating at such preferential sites is denoted as *heterogeneous* (e.g. [3, 9]) and can be described by the theoretical concepts outlined above if the work of critical cluster formation for homogeneous nucleation, W_c , is replaced by $W_c \Phi$. Here, $\Phi \leq 1$ is the nucleating activity of the heterogeneous nucleation core, and its value depends on the mechanism of nucleation catalysis. As a rule, heterogeneous nucleation dominates at small supercooling because of the lower work of critical cluster formation than that of homogeneous nucleation. At high supercooling, homogeneous nucleation dominates due to the much larger number of sites (all “molecules” of the system) where homogeneous nucleation may proceed.

The reader should note that, in certain cases, the evolution of the new phase may not proceed via the saddle shown as a dark curve in Figure 1b (in red in the colored version) but via a ridge trajectory indicated by a light curve in Figure 1b (in yellow in the colored version), if such a trajectory is kinetically favored. This type of behavior may be expected to occur in crystallization occurring at large degrees of supercooling because of the disordered and nonstoichiometric nature of the crystals that precipitate in the early stages.

Frequently, several different stable or metastable phases may be formed at some given initial state of the supercooled liquid. As Ostwald suggested (cf. [3]), in such cases the most favorable stable phase is not formed immediately. Instead, the final stable phase is reached via several stages in which different metastable phases are formed until the most stable phase is developed: this is the so-called Ostwald's rule of stages or Ostwald's step rule. As first proposed by Stranski and Totomanov (cf. [3]), this evolution path can also be explained by kinetic considerations.

3 Basic Models of Crystal Growth in Supercooled Liquids

It is now generally accepted that the properties of the crystal–liquid interface have a decisive influence on the kinetics of crystallization. Theoretical treatments of crystal growth have therefore focused closely on the interfacial structure and its effect on crystallization. With the assumption of congruent crystallization, three standard models have been developed for treating crystal growth theoretically (e.g. [10, 11]). These models are described briefly below:

- i) *Normal growth*: The interface is pictured as rough at an atomic scale. Growth takes place at step sites, which represent a sizable fraction (0.5–1.0) of the interface. Assuming that this fraction does not change appreciably with temperature, the growth rate, $u(T)$, can be expressed as

$$u = f \frac{D}{4d_0} \left[1 - \exp \left(- \frac{\Delta\mu}{k_B T} \right) \right], \quad (11)$$

where f is close to unity and $\Delta\mu$ is treated as a positive quantity.

- ii) *Screw dislocation growth*: This model assumes the interface is smooth but imperfect at an atomic scale. Growth takes place at a few step sites provided by screw dislocations that intersect the interface. The growth rate is still given by Eq. (11), where f is now the fraction of preferred growth sites (on the dislocation ledges) at the interface. In this case, f is given approximately by $f \simeq (T_m - T)/(2\pi T_m)$ [7]. More generally, according to Jackson [10], $f = (\Delta s_m/k_B)\xi$ holds, where Δs_m is the entropy of fusion per particle and ξ is the number of nearest-neighbor sites in a layer parallel to the surface divided by the total number of nearest-neighbor sites. Factor ξ is the largest for the most closely packed planes of the crystal, for which it is approximately equal to 0.5.

For $f < 2$, the minimum free energy configuration corresponds to half the available sites being filled and represents an atomically rough surface. In contrast, for $f > 2$, the lowest free energy configuration corresponds to a surface where few sites are filled and a few units are missing from the completed layer, which represents an atomically smooth interface. Hence, for materials with $\Delta s_m < 2k_B$, the most closely packed interface planes should be rough. For materials with $\Delta s_m > 4k_B$, the most closely packed surfaces should be smooth, the less tightly packed surfaces rough, and the growth anisotropy rate large.

- iii) *Surface nucleation or two-dimensional growth*: According to this model, the interface is smooth

and perfect at an atomic scale and thus free of intersecting screw dislocations and growth sites. Growth then takes place by the formation and growth of new two-dimensional nuclei at the interface. In this case, the growth rate is expressed by

$$u = C_3 \frac{D}{4d_0^2} \exp \left(- \frac{C_2}{T\Delta T} \right), \quad (12)$$

where C_2 and C_3 are parameters that determine the time required for the formation of the two-dimensional nucleus relative to that required for its propagation across the interface, respectively.

Possible growth modes are illustrated in Figure 3. Similarly to nucleation, the interplay between increasing driving force for crystallization, $\Delta\mu$, and decreasing diffusion coefficient (or increase in viscosity) with decreasing temperature results in a maximum of the crystal growth rates. This maximum is located at higher temperatures than that of the maximum of the steady-state nucleation rate shown in Figure 2c.

There are also other growth modes, which are rate limited not by processes at the liquid–crystal interface but by mass transport toward the interface. A specific example is a diffusion-limited segregation, which is of particular importance in multicomponent systems. Accounting for size effects on the growth kinetics, one can express the rate for such a growth mode as (e.g. [11, 12])

$$\frac{dR}{dt} = \frac{B}{R} \left(\frac{1}{R_c} - \frac{1}{R} \right), \quad (13)$$

Figure 3 Crystal growth rates for $\text{Li}_2\text{O}-2\text{SiO}_2$ glasses obtained by different authors. The lines correspond to the screw dislocation mechanism (full curve) and two-dimensional surface nucleated growth (dashed curve) [7].

Figure 4 Crystal morphologies formed by nucleation and growth in glass-forming liquids as observed by optical microscopy (crystal sizes from 5 to 100 μm). From top left to bottom right: (i, ii, iv) LS crystals nucleated on defects of a $\text{CaO-Li}_2\text{O-SiO}_2$ glass surface during its preparation via melting–cooling. (iii) Crystallization propagating from the surface toward the center of a $\text{CaO-Li}_2\text{O-SiO}_2$ glass specimen; lithium metasilicate crystals nucleated on two perpendicular surfaces and grew toward the sample center. (v) Surface of a $\text{CaO-Li}_2\text{O-SiO}_2$ glass sample after cooling a melt in a DSC furnace; the large-faceted and needle-like crystals are calcium and lithium metasilicates, respectively. (vi) Internal crystallization in a Ti-cordierite glass; pure stoichiometric cordierite ($2\text{MgO-2Al}_2\text{O}_3\text{-5SiO}_2$) glass underwent only surface nucleation, but the same glass doped with more than 6 mol % TiO_2 shows internal crystallization of μ -cordierite. (vii) Needle-like crystals in $\text{CaO-Li}_2\text{O-SiO}_2$ eutectic glass formed by internal crystallization in the temperature range between the *solidus* and the *liquidus*; these wollastonite crystals appear on the cooling path. (viii) Starlike NaF crystals inside a PTR glass (treatment at a high temperature near the solubility limit).

where B is a combination of parameters describing the liquid under consideration, being proportional to the effective diffusion coefficient governing the rate of supply of the different components to the growing or dissolving cluster.

Equation (13) and its modifications for other growth modes serve as a basis for the theoretical description of the competitive growth of clusters denoted as coarsening or Ostwald ripening. In these late stages of phase formation, larger clusters may grow further only when subcritical crystals are dissolved. The theoretical description of this process was first developed by Lifshitz and Slezov (cf. [11]). Today it is often referred to as the Lifshitz–Slezov–Wagner theory. This theory provides expressions for the average size, $\langle R \rangle$, and the number, N , of supercritical clusters in the system as a function of time. For diffusion-limited growth (Eq. (13)), one obtains

$$\langle R \rangle^3 \propto t, \quad N \propto \frac{1}{t}. \quad (14)$$

An account of the effect of elastic stresses on coarsening, which leads to qualitative modifications of the coarsening behavior, is reviewed in [3, 12].

The above relationships allow one to describe the growth of crystals with smooth planar or spherical interfaces advancing in the liquid. However, more complex growth patterns do exist, and more complex models of growth are required to properly take into account

possible interfacial instabilities, surface roughening, or other growth modes such as diffusion-limited aggregation [11]. With such complex growth modes, a variety of intricate and beautiful crystal shapes may evolve, some of which are illustrated in Figure 4.

4 Overall Crystallization and Glass-forming Ability: The Johnson–Mehl–Avrami–Kolmogorov Approach

The overall crystallization of supercooled liquids occurs by a combination of crystal nucleation and growth. The kinetics of such processes is usually described by a theory independently derived between 1937 and 1941 by Johnson, Mehl, Avrami, and Kolmogorov [13–17] (JMAK theory). In this approach, the evolution of the total amount of crystalline phase is described as a function of time, accounting simultaneously for nucleation and growth. The basic equations of this approach can be developed as follows.

Let us assume that, in a time interval $dt'(t', t' + dt')$, a number $dN(t') = J(t')[V - V_n(t')]$ of clusters of critical size is formed in the volume $[V - V_n(t')]$. Here, V is the initial volume of the glass-forming melt and $V_n(t')$ the volume already crystallized at time t' . These clusters grow and, at time t , occupy a volume

$$dV_n(t, t') = \omega_n J(t') (V - V_n(t')) dt' \left(\int_{t'}^t u(t'') dt'' \right)^n, \quad (15)$$

where ω_n is a shape factor and the integral term describes the growth of the $dN(t')$ clusters formed at t' until time t , i.e. in the time interval $(t-t')$, the exponent n is the number of independent spatial directions of growth. Introducing the ratio, $\alpha_n(t) = (V_n(t)/V)$, between the current volume of the crystalline phase versus the initial volume of the glass-forming melt, one has

$$d\alpha_n(t, t') = \omega_n J(t') (1 - \alpha_n(t')) dt' \left(\int_{t'}^t u(t'') dt'' \right)^n. \quad (16)$$

Integration, i.e. taking the sum over all the time intervals dt' in the range of $(0, t)$, yields

$$\alpha_n(t) = 1 - \exp \left(\omega_n \int_0^t J(t') dt' \left(\int_{t'}^t u(t'') dt'' \right)^n \right). \quad (17)$$

Provided the nucleation and growth rates are both constant, one reaches as a special case

$$\alpha_n(t) = 1 - \exp \left(- \frac{\omega_n}{(n+1)} J u^n t^{(n+1)} \right). \quad (18)$$

Conversely, if a number N_0 of supercritical clusters is formed immediately at time $t = 0$, growing in n independent spatial directions, one arrives instead at

$$\alpha_n(t) = 1 - \exp(-g N_0 u^n t^n). \quad (19)$$

The analysis of the time dependence of the $\alpha_n(t)$ -curves thus leads one to the specification of nucleation and growth kinetics.

The JMAK theory has been employed in numerous studies to analyze experimental data and determine the degree of crystallinity as a function of time in both isothermal and non-isothermal heat treatments of glass systems. Emphasis has usually been given to the determination of the so-called Avrami coefficient $m = n + 1$ obtained from the slopes of experimental $\ln[1 - \alpha]^{-1}$ versus $\ln(t)$ plots. An overview of various nucleation and growth mechanisms and the resulting values of the Avrami coefficient are given in [3]. However, there is some uncertainty in such analyses, because different combinations of nucleation and growth laws may lead to the same Avrami coefficient. For this reason, a separate investigation of the growth kinetics may be required to reach definite conclusions [14].

It is important to underline that the JMAK theory, as given by Eqs. (18) and (19), does not apply to non-isothermal processes. These two equations are derived from the assumption of constant nucleation and growth rates, which are not achieved in non-isothermal processes. Therefore, in non-isothermal cases, the general relationships, Eqs. (16) and (17), must be employed to describe overall crystallization. This requires taking into consideration not only thermal nucleation (formation of supercritical clusters due to thermal fluctuations at given values of critical cluster size and thermodynamic barrier) but also athermal nucleation (i.e. the change in the number of supercritical clusters due to the variation of the critical cluster size resulting from the change in temperature).

Such considerations must also be taken into account when the JMAK formalism is employed to determine whether a liquid will transform into a glass upon cooling or whether it will crystallize. Following Uhlmann (cf. [10]), one can consider a supercooled frozen in liquid as a glass if, after vitrification, the volume fraction of the crystal phase does not exceed a certain value of, say, 10^{-6} (the detection limit by microscopy). Using appropriate expressions for nucleation and growth rates, one can then compute (through Eq. (18) for isothermal conditions) the time required to reach the volume fractions thus defined. In this way, one arrives at the so-called $T(\text{ime})T(\text{emperature})T(\text{ransformation})$ curves (TTT curves) exemplified in Figure 5 (cf. also [18] and figure 10.8 in [3]). These curves give some insight into the characteristic timescales required to prevent measurable crystallization effects. One should keep in mind, however, that these curves overestimate the critical cooling rates for glass formation by about one order of magnitude because, as mentioned earlier, crystallization upon cooling proceeds under non-isothermal conditions.

Using experimental nucleation and growth rate data, Rodrigues and Zanotto [19] calculated TTT curves for different isothermal and non-isothermal crystallization situations. They also accounted for the breakdown of the SEE equation at a temperature T_b (somewhat higher than T_g) where the effective diffusion coefficient that controls crystal growth decouples from the value of diffusivity calculated by the SEE equation (Eq. (7)). In Figure 5 we show an example of such a curve for a stoichiometric $\text{BaO} \cdot 2\text{TiO}_2 \cdot 2\text{SiO}_2$ glass, which undergoes copious internal homogenous crystal nucleation. The agreement with experimental data (which, in this case, were also obtained in isothermal conditions) is quite impressive, indicating that the JMAK equation is accurate if all the assumptions involved in its derivation are met.

Figure 5 Simulated TTT curves for a $\text{BaO} \cdot 2\text{TiO}_2 \cdot 2\text{SiO}_2$ glass with crystallized volume fraction $\alpha = 0.05$ using, in one approach, the screw dislocation growth model both above and below T_b (t_{sd} – dashed line), and in the other the Arrhenius equation below T_b ($t_{\text{breakdown}}$ – solid line). Experimental data points (black stars) obtained at 993, 1003, 1013, and 1023 K [15].

5 Perspectives

Significant advances in the understanding and control of crystal nucleation and growth processes in glass-forming liquids have been achieved in the last five decades. It is now well-established that almost all materials can vitrify when subjected to sufficiently fast cooling from the liquid state. Thus, novel materials, such as metallic and chalcogenide glasses with unusual properties, have been obtained successfully by very fast quenching. Also, controlled, catalyzed internal crystallization of specific glasses has led to a variety of advanced glass ceramics that are now manufactured commercially. More profound insights into glass crystallization processes, such as precise predictions of nucleation and growth rates and critical cooling rates for glass formation, based solely on materials properties, will depend critically on new developments in nucleation and growth theories and computer simulations.

Despite the many advances achieved in understanding crystallization processes in glasses, some problems remain open. Among the most important, we remark the following: (i) specification of the bulk (structure, composition, density) and surface properties of the critical nuclei and sub- and supercritical crystals as a function of their sizes; (ii) description of the temperature dependence of the crystal nucleus–liquid interfacial energy and the degree of validity of the Stefan–Skapski–Turnbull equation; (iii) applicability of the SEE (viscosity) relationship in calculating the effective diffusion coefficients that control crystal nucleation and crystal growth; (vi) a clear

understanding of the causes of the breakdown of the SEE equation reported for crystal growth somewhat above T_g ; (v) unveiling the cause of the reported breakdown of the CNT in describing the temperature dependence of experimental nucleation rates below T_g ; (vi) a deeper understanding of the relationship, if any, between the molecular structure of glass-forming melts and the nucleation and growth mechanisms [20]; (vii) the relation between the sizes of supercritical nuclei vis-à-vis the sizes of cooperatively rearranging regions (CRR) of the configurational entropy theory and the domains of heterogeneous dynamics (DHD) envisaged in the structure of viscous liquids [21]; and (viii) comparison of the estimated (by extrapolation) structural relaxation time and the characteristic time for crystallization of glass-forming liquids at the (predicted) Kauzmann temperature, T_K [22, 23]. Such a comparison could resolve the paradox, following Kauzmann's suggestion of the possibility that the putative state of negative entropy may never be reached because crystallization would always intervene before structural relaxation. A detailed analysis of the Kauzmann paradox and his hypothesis about the existence of a kinetic spinodal has been performed recently [24]. In addition, the ratio of the mentioned times scales is of considerable importance concerning the problem whether some basic assumptions of CNT concerning the methods of determination of the thermodynamic driving force and the surface tension hold or not for crystallization under time-dependent temperature and/or pressure [25]. All these problems, in addition to several others not

mentioned here, such as the development of novel glasses and glass ceramics, having exotic, unusual compositions and combination of properties, serve as great incitement for glass crystallization being a very active research topic!

Acknowledgments

The authors are indebted to their numerous co-workers and students for enjoyable and educative joint research in the past 40 years and to Profs. E. B. Ferreira and F. C. Serbena for their critical comments. Generous and continuous funding by the Brazilian agencies CAPES, CNPq, and São Paulo Research Foundation, FAPESP (CEPID grant # 13/07793-6), is much appreciated.

Table of Symbols

ΔG	Gibbs free energy difference
R	cluster radius
A	nucleus surface area
N	number density of supercritical crystallites
$\Delta\mu$	chemical potential difference
μ_l	the chemical potentials per particle in the liquid
μ_{cr}	the chemical potentials per particle in the crystal
σ	surface free energy
c_α	particle number density in the crystal cluster
P	pressure
T	temperature
G	Gibbs free energy
R_c	critical radius
ΔG_c	change in the Gibbs free energy for a critical cluster
n_i	number of particles of the different components in the cluster
W_c	work of critical cluster formation
τ	time-lag in nucleation
J	rate of formation of supercritical clusters
J_s	steady-state nucleation rate
t	time
n_c	number of particles in a cluster of critical size
τ_R	Maxwellian relaxation time
η	Newtonian viscosity
t_{ind}	induction time
dN	change of number of clusters of critical size

dt	time interval
k_B	Boltzmann's constant
D	diffusion coefficient
d_0	diameter
T_m	melting temperature
Δh_m	heat of melting of one crystal phase particle
q_m	heat of melting
N_A	Avogadro's number
ζ	correction factor
f	fraction of preferred growth sites
Δs_m	entropy of melting
C_2, C_3	parameters determining the time required for the formation of the two-dimensional nucleus and for its propagation across the interface, respectively.
B	combination of parameters proportional to the effective diffusion coefficient
$\langle R \rangle$	average size of the nuclei
dt'	time interval
V	volume
V_n	volume crystallized
ω_n	shape factor
$\alpha_n(t) = (V_n(t)/V)$	time-dependent crystallized fraction
N_0	number of supercritical clusters
n	number of independent spatial directions
T_b	Stokes–Einstein breakdown temperature
T_g	glass transition temperature
T_K	Kauzmann temperature
Φ	catalytic activity factor of a heterogeneous nucleation core

Solubility of Volatiles

Bjorn Mysen

Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC, USA

1 Introduction

Even though a few hundred ppm of dissolved water may affect to a measurable extent physical properties of SiO₂ glass [1], volatile concentrations higher than 1% usually are required to exert significant effects in oxide glasses and melts. Because pressures of the order of 100 Pa are typically needed to achieve a solubility of 1 wt %, dissolution of volatiles remains a difficult and expensive task, which is hampering any practical application of the materials produced. As a result, volatile solubilities and their effects on physical properties have been mostly studied to understand the fundamental role they play in geological processes. The relevant systems are then made up of silicates along with the halogens F₂ and Cl₂, the He–Xe series of noble gases, and a number of species in the system C–O–H–N–S, namely, H₂O, H₂, CO₂, CO, CH₄, N₂, NH₃, SO₂, S, and H₂S. To illustrate in this chapter the manner in which the structure and physical and chemical properties of silicate glasses and melts change upon volatile dissolution, we will review experimental data from systems that are comparatively simple (unary to quaternary) with extrapolation to more complex chemical environments when appropriate.

2 Principles and Concepts

2.1 Reactive and Nonreactive Solubility

The solubility of volatiles in a silicate structure and its effects on it depend on gas and silicate compositions

together with temperature, pressure, and redox conditions (as generally specified by oxygen or hydrogen fugacity). The sensitivity to the interplay of these conditions is illustrated by the fact that, under reducing conditions, species such as CH₄ and NH₃ may form in the presence of hydrogen, whereas formation of carbides and nitrides takes place instead if hydrogen is lacking in the melt. These examples also illustrate the generally *reactive* nature of volatile dissolution, where the volatile species forms chemical bonding with the silicate structure and in the process affect the properties of the material. Examples include H₂O, which forms OH groups. The CO₂ and SO₂ form CO₃ and SO₄ groups, respectively, by sharing oxygen with the silicate. In other structural interactions, oxygen in the silicate structure can be replaced with functional groups such as CH₃ from methane and NH₂ from ammonia and S-bearing groups from H₂S. Exchange of oxygen in the silicate tetrahedra with C, N, or S can also occur. In addition, water, carbon dioxide, ammonia, and methane can dissolve either as molecular or *nonreactive* molecular species together with a reactive portion (e.g. OH groups and H₂O) whose proportions also depend on all intensive thermodynamic variables. Species that dissolve only in molecular and nonreactive form at noble gases and N₂.

Although it is possible to dissolve volatiles in glasses, most experimental studies have been performed on melts, which were then temperature-quenched to glass to ascertain that an equilibrium state was actually reached and to give sound basis to thermodynamic modeling of the solution process. In this chapter we will thus restrict ourselves to these conditions. It is implied, therefore, that the volatile species have equilibrated with the silicate structure under specific temperature, pressure, and redox conditions before the melt is quenched to a glass. Two kinds of experiments must be further distinguished depending on whether the melt is undersaturated or saturated with

Reviewers: K.-U. Hess, Earth and Environmental Sciences, Ludwig-Maximilians-Universität, Munich, Germany
A. Whittington, Geological Sciences, University of Missouri, Columbia, MO, USA

the volatile of interest. In the latter case, equilibration between the volatile in the melt and in a coexisting gas phase is of course necessary.

2.2 Glass Versus Quenched Melt

The physics of the glass transition is discussed elsewhere (Chapter 3.3). Here, we will address only how, or the extent to which, volatiles dissolved in melts may be quenched in the glass structure and whether, or the extent to which, the structure of volatile components in glass is a viable representation of the structural environment of volatile-containing silicate melts.

The solubility in melts of the individual volatile species considered in this chapter differs significantly, is slightly temperature dependent, and is often a pronounced function of pressure (Table 1). As a result, a melt must be decompressed and cooled down from the equilibrium conditions either to synthesize a glass with a desired volatile content or in order to examine a volatile-bearing glass as a proxy for its melt. In order to retain the volatile content in the quenched glass of the high-temperature/pressure melt, the quenching rate must exceed the rate at which volatiles may exsolve. The exsolution rate depends primarily on the diffusivities of volatiles and the nucleation rate of gas bubbles in the cooling melt. Furthermore, equilibria between different functional groups of volatile species in principle depend on both temperature and pressure. Therefore, when studying volatiles in glass, it must be kept in mind that volatile contents and their solution mechanism may have been affected by the glass-forming process.

2.3 Intensive Variables (Pressure, Temperature, Redox Conditions)

A description of the principles that govern silicate–volatile equilibria at temperatures above the liquidus is useful for

Table 1 Solubility (mol %) of H₂O, CO₂, and SO₂ in NaAlSi₃O₈ composition melt near 1500 °C as a function of pressure (GPa).

Pressure (GPa)	H ₂ O	CO ₂	SO ₂
0.5	59	4.2	1.6
1.0	78	6.1	2.1
1.5	82	7.6	2.5
2.0	84	8.2	2.8
2.5		9.0	3.1
3.0		9.6	3.3

Source: data summary from [2].

understanding relationships between composition, temperature, and pressure (Figure 1). At a given pressure, there exists a temperature range from the solidus (a eutectic point is used for this illustration in Figure 1) to a critical point (*c. p.*), where a melt is saturated with respect to the volatile component of interest. In this temperature range, a solvus separates the stability field of volatile-saturated melt+volatile-rich fluid and the boundary between volatile-rich fluid and volatile-saturated melt. The former boundary defines the solubility of the volatile component(s) in the melt. At temperatures above the critical point, there is no distinction between melt and fluid. The width and height of the solvus (in the temperature–composition space illustrated in Figure 1) diminish with increasing pressure.

The solubility of volatiles in silicate melts is sensitive to pressure. As already stated, it often can increase from only a few hundred ppm at ambient pressure to several mol % at several hundred MPa. Water is an example of such a component. The effects of temperature are generally smaller, but remain significant, and can also be dependent on pressure. As for redox conditions, they also affect the silicate–volatile phase relations through their influence on volatile speciation. For example, the solubility of CH₄ is less than half of that of CO₂ for a given silicate composition, temperature, and pressure. Ammonia (NH₃) solubility, on the other hand, can be several times higher than that of N₂.

Figure 1 With water as an example, schematic representations of phase relations in silicate + volatile systems. Only a simple eutectic defines the minimum temperature of melting and a simple solvus separating volatile-bearing melt from silicate-bearing fluid, which determines the solubility of volatile component as a function of temperature at given pressure. The width of the solvus depends on pressure and silicate composition and can also vary with redox conditions.

2.4 Composition

Silicate and gas composition affect solubility and solubility mechanisms of volatiles in melts. When a multicomponent gas coexists with a melt with which it is completely miscible, the gas composition is enriched in the component that is least soluble in the melt. Examples are silicate–H₂O–CO₂ mixtures because the solubility of CO₂ in silicate melts is only a small fraction of that of H₂O (see Table 1). When gas speciation is redox dependent, the fractionation of the components between the melt and coexisting gas will also vary with redox conditions. The activity–composition relations in the gas phase also can play an important role.

As defined above, volatile solution is nonreactive when it is governed by the availability and dimensions of the cavities (structural locations) in the structure that are occupied by the volatile molecules. Then the degree of melt polymerization (NBO/Si; see Chapter 2.6) is the most important variable affecting this solubility because the more polymerized a silicate melt and glass, the greater the availability of cavities thanks to the larger proportion of rings made up of SiO₄ tetrahedra. An example is silica-rich compositions where Q⁴ species are the dominant structural components (three-dimensionally interconnected network of silicate tetrahedra). Moreover, for a given silicate melt, temperature, and pressure, the solubility increases as the atomic or molecular radius of the nonreactive element or compound decreases. Examples are noble gases (He–Xe) and N₂.

When the dissolved volatile component interacts chemically with the silicate, its solubility depends on the availability of bridging and nonbridging oxygen and on the electronic properties of network-forming and network-modifying cations. When cations serve to charge-balance tetrahedrally coordinated Al³⁺, the nature of the charge-balancing cations also affects solubility and solution mechanisms. In addition, silicate composition affects the temperature- and pressure-dependent solubility of the volatile components such as OH[−], CO₃^{2−}, SO₃^{2−}, NH₂[−], and CH₃.

3 Reactive Volatiles in Silicate Glass and Melt

Except noble gases and molecular nitrogen, all the volatiles considered in this chapter are reactive. Other volatiles may dissolve in a manner that includes both reactive and nonreactive species (e.g. molecular H₂O vs. OH groups and CO₂ vs. CO₃ groups).

3.1 Hydrous Glass and Melt

Among the volatiles discussed in this chapter, dissolved water has the most profound influence on glass and melt

structure and properties. Its solubility in silicate melts is also greater than that of any of the other volatiles except, perhaps, fluorine.

3.1.1 Solubility and Solution Mechanisms

When quenched from a hydrous melt, glasses have water contents varying from a few hundred to a few thousand ppm at ambient pressure to several tens of mol % at pressures in the MPa–GPa range. In silicate–H₂O systems, there exists a maximum pressure and temperature above which complete water miscibility obtains, which defines the critical point (c.p., shown schematically in Figure 1). The pressure/temperature coordinates of the critical point are sensitive functions of silicate composition and range from about 1 GPa/600 °C for Na silicates to >5 GPa/>1100 °C for Mg silicates. The electronic properties (ionization potential) of the metal cation appear the most important variable affecting the pressure/temperature coordinates of the critical point.

Below the critical point (c.p. in Figure 1), the solubility of H₂O is a strongly nonlinear and positive function of total pressure and a positive or negative function of temperature depending on pressure and silicate composition (Figure 2). In addition, water solubility strongly depends on silicate composition, being a negative function of Al/(Al+Si) and of the ionization potential, Z/r^2 , of the metal cation (Z : formal electrical charge, r : ionic radius). In

Figure 2 Isothermal solubility of pure water in various silicate melts as a function water pressure, $P_{\text{H}_2\text{O}}$. Trachyte (data from [3]) a natural magma composition ($\text{SiO}_2 = 61.71$ wt %, $\text{Al}_2\text{O}_3 = 18.56$, $\text{FeO} = 3.17$, $\text{MnO} = 0.27$, $\text{MgO} = 0.23$, $\text{CaO} = 1.64$, $\text{Na}_2\text{O} = 6.11$, $\text{K}_2\text{O} = 7.09$), AOQ (data from [4]) are for a model composition ($\text{SiO}_2 = 76.14$ wt %, $\text{Al}_2\text{O}_3 = 13.53$, $\text{Na}_2\text{O} = 4.65$, $\text{K}_2\text{O} = 5.68$). Solubility data for SiO_2 melt are from [5].

contrast, water solubility in aluminosilicate melts increases with the electronegativity of the cation that charges compensate Al^{3+} in tetrahedral coordination (see Chapter 2.6).

Under equilibrium conditions the high-pressure and temperature solution mechanisms of water vapor in silicate melts have been described by the expression

where the abundance ratio of molecular water, H_2O° , to structurally bound OH groups, $\text{H}_2\text{O}^\circ/\text{OH}$, varies because the proportion of molecular H_2O increases with increasing total water content (Figure 3). For glasses, the $\text{H}_2\text{O}^\circ/\text{OH}$ ratio is insensitive to temperature, but above the glass transition, equilibrium (1) shifts to the right with a ΔH around 30 kJ/mol.

The O^{2-} in Eq. (1) is the structural link between the water speciation and silicate structure. In its simplest form, such as in the system $\text{SiO}_2\text{--H}_2\text{O}$, the OH groups are formed by breaking the oxygen bridges in the three-dimensional network structure of silica glass and melt:

where SiO_2 is represented as Q^4 and $\text{Q}^3(\text{H})$ denotes a Q^3 species with protons serving as network-modifying cation (see Chapter 2.4 for discussion of Q^n species in silicate glasses). In chemically more complex silicate glasses, OH groups also bond with Al^{3+} , alkali metals, and alkaline

Figure 3 Speciation of water as molecular H_2O and OH groups in melts of compositions indicated as a function of bulk (total) water content. Data for $\text{Na}_2\text{Si}_4\text{O}_9$ glasses quenched from 1100 °C at 200 MPa (data from [6]) and for $\text{NaAlSi}_3\text{O}_8$ glass quenched from 1400 °C and 1.5–2.0 GPa (data from [7]).

earths, thus creating more complex relations between the structure, composition, and solubility and solution mechanisms of water in silicate melts and glasses (Figure 2).

3.1.2 Structure–Property Relations

Transport, volume, and thermodynamic properties of silicate glasses and melts significantly depend on water content because of the alteration of the silicate structure caused by formation of OH groups. Viscosity, electrical conductivity, and diffusion are quite sensitive, so about 1 wt % water, for example, can lower melt viscosity by several orders of magnitude. Increasing water content also results in increasing configurational entropy, lower glass transition temperature, and lower melting temperatures (see data review in [1], Chapter 14). These variations are partly due to formation of depolymerized Q^n species upon water dissolution. Similar reasoning explains increased diffusivity of water at higher water contents.

3.2 Oxidized Carbon (CO_2)

Carbon is the second most abundant element of the C–O–H–N–S system in Earth. In the C–O–H subsystem, CO_2 at the temperature of molten silicates is stable down to oxygen fugacities about three to four orders of magnitude lower than that of air.

3.2.1 Solubility and Solution Mechanisms

The solubility of CO_2 in silicate melts at ambient pressure is lower than 0.1 wt %, but it increases rapidly with pressure and also varies with the water content of the melt sometimes with a maximum CO_2 solubility at intermediate $\text{CO}_2/\text{H}_2\text{O}$ abundance ratios. The solubility of CO_2 is less than 10 % of that of water under otherwise identical silicate composition, temperature, and pressure, and it depends more strongly on melt composition. Of particular importance are polymerization (NBO/T) and the electronic properties of the network-modifying cations (alkali metals and alkaline earths) (Figure 4). There is a positive correlation of CO_2 solubility with NBO/T whether in chemically simple or more complex silicate compositions [9]. The $\text{Al}/(\text{Al}+\text{Si})$ ratio and metal cation types and proportions also affect the solubility.

From vibrational (Raman and FTIR) and carbon-13 NMR spectroscopy of quenched, CO_2 -saturated melt (glass), carbon dioxide is found to dissolve in the form of CO_3^{2-} complexes and molecular CO_2 . The expression, which is analogous to that describing the $\text{H}_2\text{O}/\text{OH}$ relationships in silicate glasses and melts (Eq. (1)), is

Figure 4 Solubility of carbon dioxide in CaO–MgO–Al₂O₃–SiO₂ melts determined in glass quenched from 1275 to 1600 °C at 1.5 GPa as a function of the degree of polymerization of the melt (NBO/T, where T = Al³⁺ + Si⁴⁺) (data from [8]).

Here, as for water, the O²⁻ is the link to the silicate structure. This link can be replaced by Qⁿ-species equilibria to yield

This equilibrium is sensitive to bulk composition and shifts to the right with increasing metal oxide/SiO₂ and Al/(Al+Si) ratio ([1], Chapter 16). In mixed CO₂/H₂O environments, decreasing CO₂/H₂O in coexisting gas also shifts this equilibrium to the right. Available information indicates that at temperatures above the glass transition, equilibrium (3) shifts to the left with increasing temperature and decreasing pressure (Figure 5).

Figure 5 Calculated proportion of molecular CO₂ and carbonate groups, CO₃, in melt of basalt composition as a function of temperature and pressure (calculations by [10]). See also Chapter 2.6 for further discussion of basalt composition.

3.2.2 Structure–Property Relations

Solution of carbon dioxide in glasses and melts results in increased Qⁿ⁺¹/Qⁿ abundance ratio in the silicate, i.e. the network becomes increasingly polymerized (Eq. (4)). This is the opposite of the effect of dissolved water, which causes the silicate network to depolymerize (Eq. (2)). Therefore, melt and glass properties that vary with melt polymerization will also vary with the concentration of dissolved carbon dioxide. This change will, for example, cause expansion of more polymerized liquidus phases compared with CO₂-free systems. Moreover, configurational heat capacity and entropy would tend to decrease because the partial molar heat capacity of the more polymerized Qⁿ species is smaller than that of depolymerized Qⁿ species. It follows that transport properties will also change with proportion of dissolved carbon dioxide. Experimental data relevant to these important properties are, however, scarce, so many of these predictions cannot as yet be benchmarked against experimental data.

3.3 Reduced Carbon

The reduced carbon species of interest in the C–O–H subsystem of volatiles are CO, C, and hydrocarbons. Among possible hydrocarbons, only CH₄ is found stable under the temperature/pressure conditions of melt precursors of silicate glass.

3.3.1 Solubility, Solution Mechanisms, and Properties

Solubility and solution mechanisms for elemental C in silicate melts and glasses are not well established. By analogy with C solubility in crystalline silicates, it is likely of the order of tens of ppm. This oxidation state, therefore, will not need to be considered further. Likewise, little can be said about carbide solubility and solution mechanisms in silicate–C–O melts, which would obtain in highly reducing, H-free environments but have not been examined to any significant extent.

Carbon monoxide, CO, predominates in the C–O system at the temperatures of molten silicates within comparatively narrow oxygen fugacity range of about 2 log units. The solubility ranges from <100 ppm at ambient pressure and high temperature to 1–2 wt % in the 2–3 GPa range (Figure 6) and is highest at the graphite saturation surface. Experimental data with which to address the effects of silicate composition are not available. From less than a handful of existing experimental studies, however, it appears that the solubility of CO in silicate melts is lower than that of CO₂ at the same pressure, temperature, and silicate compositions. The difference can reach 50 % and decreases with increasingly melt polymerization.

Solution of CO in silicate melts in equilibrium with essentially pure CO gas results in formation of CO₃²⁻-type complexes. However, the exact solution

Figure 6 Solubility of CO₂ and CO in melts in equilibrium with either pure CO₂ fluid or mixed CO+CO₂ fluid for the silicate compositions indicated as a function of total pressure at 1700 °C (data compilation by [1]).

mechanism(s) is not clear as this process requires reduction of one or more of the silicate components. This redox couple has not been identified yet.

In silicate–C–O–H systems, methane (CH₄) is the dominant C-bearing gas species under highly reducing conditions. Methane solubility in silicate melts is 60–80% less than that of CO₂ (Figure 7). Methane solution mechanisms, determined by ¹³C MAS NMR and by Raman spectroscopy of glass formed by temperature quenching of melt at high pressure (1–2 GPa), involve methyl groups (CH₃) and molecular CH₄ whose proportions vary with melt composition. An expression to describe the solution mechanism of methane in silicate melts is

In Eq. (5), the Qⁿ species are as described in Chapter 2.2. The notations (CH₃) and (OH) indicate that CH₃ and OH groups form Si–CH₃ bonds in depolymerized Qⁿ⁻¹ species. In principle, this mechanism has many similarities with that described for H₂O (Eq. (2)). It is not surprising, therefore, that dissolved methane affects liquidus phase relations in silicate systems much as does dissolved water. On an equimolar basis, the effect on liquidus temperatures is also about the same as that of water (~10 °C/mol % CH₄ or H₂O).

3.4 Reduced Nitrogen

Nitrogen in silicate melts can be reactive or nonreactive, depending on its oxidation state. Molecular N₂ is stable under oxidizing conditions such as those of air and down to perhaps two to three orders of magnitude lower oxygen fugacity. Because it is nonreactive, it will be described further in Section 4. Under more reducing conditions,

Figure 7 Solubility of oxidized and reduced carbon as a function of Na/Si ratio of Na₂O–SiO₂ melts at 1400 °C and pressures between 1 and 2.5 GPa under either oxidizing or reducing conditions (hydrogen fugacities defined by the 3 Fe₂O₃ + H₂ = 2 Fe₃O₄ + H₂O or FeO + H₂ = Fe + H₂O equilibria, respectively).

nitrogen is more soluble than oxidized nitrogen in silicate–N–O systems. It forms nitride complexes presumably by exchanging with oxygen in silicate tetrahedra, but possibly also with other metal cations, and gives rise to the original oxynitride glass family (see Chapter 7.8). In silicate–N–O–H systems, the nitrogen solubility increases with increasing hydrogen fugacity, *f*_{H₂}, at given temperature and pressure (Figure 8). In such melts, nitrogen and hydrogen react to form ammonia, NH₃, which is nonreactive in silicate melts, and NH₂ groups linked to Si⁴⁺ with resultant breakage of Si–O–Si bridges in the structure

where (NH₂) and (OH) indicate that NH₂ and OH groups bond with Si⁴⁺ in the depolymerized Qⁿ⁻¹ species. In principle, this mechanism resembles that described for H₂O (Eq. (2)) and methane (Eq. (5)). Although little or no experimental data exist with which to characterize the effects of reduced nitrogen on melt and glass properties, we can expect that nitrogen dissolved as NH₂ groups has effects resembling those of dissolved water and methane.

Figure 8 Solubility of nitrogen in quenched $\text{Na}_2\text{Si}_4\text{O}_9$ melt as a function of pressure under the redox conditions indicated. Hydrogen fugacity buffered by the reactions; $3 \text{Fe}_2\text{O}_3 + \text{H}_2 = 2 \text{Fe}_3\text{O}_4 + \text{H}_2\text{O}$ (MH), $\text{NiO} + \text{H}_2 = \text{Ni} + \text{H}_2\text{O}$ (NNO), $\text{Fe}_3\text{O}_4 + \text{H}_2 = 3 \text{FeO} + \text{H}_2\text{O}$ (MW), and $\text{FeO} + \text{H}_2 = \text{Fe} + \text{H}_2\text{O}$ (IW), where the f_{H_2} (IW) $>$ f_{H_2} (MW) $>$ f_{H_2} (NNO) $>$ f_{H_2} (MH) at the same temperature and pressure.

3.5 Sulfur

Sulfur can exist in at least four different oxidation states (S^{6+} , S^{4+} , S^0 , and S^{2-}). Among these, the solubility of elemental sulfur in silicate melts and glasses is likely so small that it will not be considered further. For the other oxidation states, the solubility may reach thousands of ppm while depending on bulk silicate composition, temperature, pressure, and sulfur fugacity, f_{S_2} , and oxygen fugacity, f_{O_2} .

Whether under reducing or oxidizing conditions, sulfur solubility is a positive function of the metal oxide/ SiO_2 ratio of the glass (Figure 9). At constant silicate composition, it first decreases with increasing f_{O_2} and then increases because different solution mechanisms operate for the different redox states. On the oxidizing side of the minimum, one has

where decreasing f_{O_2} results in decreasing sulfur solubility (as SO_4^{2-} groups). On the reducing side of the minimum, the sulfur solubility, now as S^{2-} groups, increases with decreasing f_{O_2} :

These relations can be expanded to describe sulfur speciation with the silicate Q^n species:

Figure 9 Sulfur solubility in Na_2O - SiO_2 melts as a function of redox conditions in glasses quenched from 1200°C and at ambient pressure (data from [11]).

and

In these expressions, M^{m+} denotes network-modifying cations that also serve to charge compensate the S-bearing functional group.

Expressions (8a) and (8b) illustrate how the redox state of sulfur species is linked to the degree of silicate melt polymerization (here expressed as the abundance ratio, $\text{Q}^{n+1}/\text{Q}^n$). In both cases, decreasing melt polymerization, $\text{Q}^n/\text{Q}^{n+1}$, drives the equilibrium toward the higher solubility, which is as observed.

These same two expressions point to how properties of the M^{m+} cation(s) govern sulfur solubility. This feature is often expressed as sulfur capacity, C_s , which is defined as $C_s = W_{\text{t}_i}(f_{\text{O}_2}/f_{\text{S}_2})$ and embodies the fact the relative stability relations of $\text{Q}^n(\text{M}^{m+})$ and the sulfur species exert strong control on sulfur solubility. This feature has important metallurgical implications that are discussed in Chapter 7.4.

3.6 Halogens

Fluorine and chlorine are the two halogens that have received most attention. Structural and property data are much more extensive for F-bearing than for Cl-bearing glasses and melts in part because fluorine has a quite high solubility even at ambient pressure and because it exerts major effects on glass properties. It is

often assumed that these features are due to the fact that F^- can substitute for O^{2-} in the silicate network in simple systems such as SiO_2-F , having in this sense a role similar to that of OH^- upon water dissolution. For physical properties such as viscosity and liquidus phase relations, however, addition of fluorides to silicate glasses and melts often has substantially different impact on properties compared with that of equimolar proportions of dissolved water.

The solubility of chlorine generally is lower than that of fluorine. Effects of bulk composition on solubility also differ because variations in metal cation type and $Al/(Al+Si)$ ratio, for example, have significantly greater effects on fluorine than on chlorine solubility. Furthermore, the functional relationships between melt composition and solubility differ for the two halogens whose effects on melt and glass properties are quite different. Chlorine barely causes viscosity changes, whereas the effects of fluorine are often of the same magnitude as those of dissolved water. Melting temperatures and melting phase relations are also affected in different ways where, on an equimolar basis, fluorine causes greater freezing point depression than H_2O and is more effective than Cl by several hundred percent.

There are important differences in the solution mechanisms of fluorine in SiO_2 , in metal oxide/ SiO_2 , and in metal oxide/ Al_2O_3/SiO_2 melt and glass systems. The simple SiO_2-F system comprises $Si-F$ bonds, whereas, as determined from ^{19}F MAS NMR data, the dominant solution mechanism in metal oxide/ SiO_2 systems is simple metal fluoride complexing. In aluminosilicate melts, the solution mechanism involves charge-balanced Al^{3+} and Si^{4+} , where the relative import of Si^{4+} and Al^{3+} in the F-bearing complexes correlates with the original Si/Al ratio. In comparison with hydrous metal oxide/ SiO_2 glasses and melts, the metal fluoride complex plays a more important role in the structure than metal oxide- OH complexes [12]. For chlorine, the dominant solution mechanism is interaction between Cl^- and alkali metals or alkaline earths. If there is direct interaction with the rest of the silicate structure, these effects are of subordinate importance.

3.7 Hydrogen

Hydrogen solubility data exist for only a few melt and glass compositions, namely, SiO_2 glass, $NaAlSi_3O_8$ melt, and $CaMgSi_2O_6$ melt. In SiO_2 glass, hydrogen solubility is a linear function of pressure and is comparable to those of the noble gases in silicate melts. These data are consistent with solution of H_2 in molecular form. However, at higher

temperature and pressure, the H_2 solubility is proportional to the square root of pressure, which points to chemical interaction between the dissolved hydrogen and the silicate structure. The freezing point depression of silicate caused by H_2 -rich fluids also suggests that hydrogen interacts chemically with the silicate melt structure [13].

4 Nonreactive Volatiles in Silicate Glass and Melt

The nonreactive volatiles in silicate glasses and melts are the noble gases and molecular N_2 . As already stated, solution of hydrogen, water, carbon dioxide, and methane partly takes place in the form of nonreactive species. In melts and glasses containing several percent or more water, more than 50 % of this water is dissolved in the molecular form H_2O . However, as noted above [Section (3.1)], the proportion of molecular H_2O decreases with increasing temperature above the glass transition. Molecular CO_2 and CH_4 likely also vary with temperature, but few experimental data are available. The proportion of the molecular form is also quite sensitive to bulk composition, so for both the methane and carbon dioxide systems, the more important the molecular and nonreactive forms, the more silica-rich (more polymerized) a melt.

For volatiles that exist exclusively in molecular form in silicate melts and glasses (inert gases and N_2), there is a simple relationship between solubility and atomic or molecular dimensions (Figure 10). Near ambient

Figure 10 Solubility of nonreactive gases in tholeiite basalt melts at ambient pressure and 1350 °C as a function of atomic/molecular diameter (data from [14, 15]).

pressure, the noble gas solubility, X_i , is proportional to its concentration in the gas phase, P_i , via a proportionality constant, K_i :

$$X_i = K_i P_i. \quad (9)$$

So the K_i value (Henry's law constant) for a given silicate composition is negatively correlated with the atomic radius of the noble gas. This constant increases with silica content of the melt.

The temperature dependence of noble gas solubility is slight and can be either positive or negative, whereas the K_i value decreases nonlinearly with pressure. The deviation from linearity increases with pressure and with noble gas atomic radius. In natural silicate melts, the enthalpy of solution, ΔH_s , ranges from near 5 to about 20 kJ/mol and decreases with increasing atomic radius. This enthalpy becomes increasingly sensitive to melt polymerization (equivalent to metal/silicon ratio) as the atomic radius of the noble gas increases.

The solubility mechanism or mechanisms of noble gases in silicate melts and glasses have been modeled with the assumption that the gas occupies holes in the structure. For example, the partial molar volumes obtained from solubility measurements estimate the porosity of SiO_2 glass. The partial molar volumes in silica glass are 16.4 ± 1.4 , 10.3 ± 2.3 , and $5.5\text{--}10.8 \text{ cm}^3/\text{mol}$ for Ar, Ne, and He, respectively.

5 Perspectives

Many volatile components commonly dissolve in the form of simple anionic complexes (e.g. OH groups, CO_3 groups, etc.). To develop an understanding of how volatiles affect structure and properties of glasses and melts, however, it is necessary to establish how these reactive functional groups interact with the silicate structure. This goal may now be attainable with the aid of modern spectroscopic methods. Ideally, such characterization should be conducted while the samples are at the temperatures and pressures of interest because temperature quenching and decompression of a melt can lead to changes in both concentration of the volatile component(s) and their structural interaction. Numerical simulations of solution mechanisms also show promise and likely will become more important in the future as computational capacities and speed advance. For nonreactive solution, such approaches will, for instance, picture how "inert" gases contribute themselves to the formation of the cavities in which they are accommodated. Integrated

examination that combines simulation with *in situ* experiments will add further to the development. Technology has slowly becoming available with which at least structural characterization at high temperature and pressure can be carried out. Solubility data may also be obtained in this manner, provided that the temperature and pressure effects necessary to translate instrumental information into solubility are known. For example, infrared absorption can be conducted with melts, but temperature and pressure effects on molar absorption coefficients are poorly known. The principles are beginning to emerge and will give a sounder basis to thermodynamic modeling of volatile–melt equilibria (Chapter 5.3).

Redox Thermodynamics and Kinetics in Silicate Melts and Glasses

Reid F. Cooper

Department of Earth, Environmental and Planetary Sciences, Brown University, Providence, RI, USA

1 Introduction

Size and charge are first-order considerations of the cation role in the structure of ionic melts and glasses. But many cations, particularly of transition metals, are heterovalent, that is, the cation charge and size are affected by the chemical potential of the oxidizing elements. Consequently, redox potential becomes not only (i) a tool in engineering the properties of synthetic melts and glasses but also (ii) a variable in the service properties of formed glasses, both synthetic and natural.

The thermodynamics involved in the study of redox are reasonably straightforward, the caveat being the standard one for multicomponent solutions, i.e. the need to know the relationship between component activity and component concentration. Redox dynamics, i.e. the coupling of thermodynamics with kinetics, are more complicated. Here, dynamics are considered from two end-member perspectives: *closed systems*, where the redox potentials of various component cations interact on a short time-scale such that reactions are local (nominally at atomic scale), and *open systems*, in which the structural state of the melt or glass is being modified dynamically by an external redox potential. The establishment and control of color in glass or the use of redox reactions in glassmelt fining are examples of the former, while the float-glass process and the ambient-environment “weathering” of synthetic and natural glasses are examples of the latter. The heterovalency of ions (both of cations and some anions, e.g. those of sulfur) effects semiconductor properties in the melts/glasses, which is important in both closed- and open-system contexts.

In what follows, redox thermodynamics are considered from the perspective of the chemical potentials/activities of oxides and not of ions. As learned from Hermann Schmalzried [1], this is distinctly practical: one can control straightforwardly the activities of oxides (and of other neutral elements or compounds) in experimental and production settings; the same is not true for the activities of ions. Nevertheless, one can consider redox based on an ion-activity perspective (e.g. Chapter 5.9). Additionally, for simplicity, this chapter emphasizes silicate glassmelts and glasses. The extrapolation of the ideas and approach presented here to SiO₂-free oxide and halide melts and glasses is straightforward. The challenge is almost always in having good, useful solution models for these complex multicomponent systems.

2 Oxidation/Reduction Thermodynamics

2.1 Reference Reactions: Pure Metal to Pure Metal Oxide; Pure Oxide to Pure Oxide of Different Valence

The relative oxidation potentials of the various elements are the natural starting point for treating redox reactions in multicomponent melts and glasses. One can discern them by examining the reference reactions in which a pure metal reacts with pure molecular oxygen. Because we are interested in relative potentials, the reactions should each be written in terms of one mole of O_{2(g)}, i.e.

Reviewers: D.L. Kohlstedt, Department of Earth Sciences, University of Minnesota, Minneapolis, MN, USA
A. Pommier, IGPP, Scripps Institution of Oceanography, La Jolla, CA, USA

where, applying the law of mass action, one expresses the equilibrium constant K_{eq} as

$$K_{\text{eq}} = \frac{[a_{\text{M}_x\text{O}_y}]^{1/y}}{[a_{\text{M}}]^{x/y}[a_{\text{O}_2}]} = \exp\left(\frac{-\Delta_r G_{(1)}^\circ}{RT}\right). \quad (2)$$

In Eq. (2), a_i is the activity of species i , RT has the usual meaning, and $\Delta_r G_{(1)}^\circ$ is the standard Gibbs free energy of reaction (1), “standard” because reaction (1) involves “pure” reactants creating “pure” products, i.e. no solutions are involved. At equilibrium, the metal M and the metal oxide are both present: $a_{\text{M}} = a_{\text{M}_x\text{O}_y} = 1$; consequently, Eq. (2) can be rewritten as

$$\Delta_r G_{(1)}^\circ(T) = -RT \ln K_{\text{eq}} = RT \ln a_{\text{O}_2}. \quad (3)$$

At low pressures, the activity of oxygen is equivalent to the partial pressure, p_{O_2} (in atmospheres). As stated by the Gibbs phase rule, for a pure metal–pure metal oxide in equilibrium, two phases coexist in a two-component system, so Eq. (3) is directly employed to define the metal–metal oxide buffer for oxygen.¹ At elevated pressures the formalism remains the same, but one must use instead G.N. Lewis’ fugacity function, i.e. $\Delta_r G_{(1)}^\circ(T) = RT \ln f_{\text{O}_2}$, if the relationship between fugacity and activity is known.

In Eqs. (2)–(3), $\Delta_r G_{(1)}^\circ$ has enthalpic and entropic components, i.e. $\Delta_r G_{(1)}^\circ = \Delta_r H_{(1)}^\circ - T\Delta_r S_{(1)}^\circ$, where H and S of each reactant and of the product in reaction (1) are both functions of temperature: at any specified T , then, $\Delta_r H_{(1)}^\circ$ and $\Delta_r S_{(1)}^\circ$ can be calculated via integration of $\Delta_r C_p(T)$ and $\Delta_r C_p(T)/T$, respectively, where C_p is the isobaric heat capacity, which is, in general, a nonlinear function of T . To the $\Delta_r G_{(1)}^\circ(T)$ so calculated, a function can then be adjusted, typically of the form $\Delta_r G_{(1)}^\circ(T) = A + BT \log T + CT$, where A , B , and C are constant fit parameters. Tables of such data for standard oxidation reactions are readily available in the literature (e.g. [2, 3]).

A graph of $\Delta_r G_{(1)}^\circ(T)$ [$= RT \ln a_{\text{O}_2} = RT \ln (p_{\text{O}_2}, \text{atm})$] vs. T is presented as Figure 1 (after [4] and the references therein). This type of plot is known as an Ellingham

diagram; the additional axis for the oxygen activity (partial pressure in atm) is explained below.² Because the reactions follow the form of reaction (1), i.e. each in terms of 1 mol of $\text{O}_{2(\text{g})}$ reactant, the relative oxidation potentials of metals and of transition metal oxides are revealed, with more negative values of $\Delta_r G_{(1)}^\circ$ representing a greater oxidation potential (i.e. a more stable oxide). Immediately obvious is that the data for each reaction plot essentially as a straight line (or a continuous series of straight lines with slope changes corresponding to phase changes of the reactants and/or products): the temperature sensitivity of $\Delta_r G^\circ$ is the blatant one associated with the relationship $\Delta_r G^\circ = \Delta_r H^\circ - T\Delta_r S^\circ$, that is, the temperature sensitivities of $\Delta_r H^\circ$ and $\Delta_r S^\circ$ are revealed as second-order effects. As such, the slopes of the solid metal-to-solid metal oxide “curves,” for example, indicate that the entropy decrease associated with incorporation of a mole of O_2 gas into a crystalline solid is approximately -185 J/mol/K . In passing, note that a reaction in which 1 mol of $\text{O}_{2(\text{g})}$ reacts with a solid to produce 1 mol of a gaseous oxide, e.g. $\text{C} + \text{O}_{2(\text{g})} = \text{CO}_{2(\text{g})}$, has approximately a zero slope, whereas one in which 2 mol of product gas are formed, e.g. $2 \text{C} + \text{O}_{2(\text{g})} = 2 \text{CO}_{(\text{g})}$, has a negative slope. The highest values on this Ellingham diagram correspond to elements such as Cu, Fe, Ni, Co, and also Au, Ag, and the platinum-group elements considered by geochemists to be *siderophile* (literally, iron loving); the lowest values are, in contrast, for elements such as Ca, Al, Li, Ti, and Si that are considered as *lithophile* (rock loving).

One ramification of plotting $RT \ln (p_{\text{O}_2}, \text{atm})$ vs. T is that any straight line that goes through the origin of the graph, $\Delta_r G_{(1)}^\circ = 0$ and $T = 0 \text{ K}$ (the point labeled as O in the upper left-hand corner of the diagram), has a slope of $R \ln p_{\text{O}_2}$, i.e. it is a line of constant oxygen activity: this is the foundation of the farthest-out external scale (along the graph’s right-hand side and bottom) labeled p_{O_2} . The straightforward way to use the graph is to evaluate the slope of a line emanating from the origin through the point where a specific $\Delta_r G_{(1)}^\circ$ reaction curve intersects a specified temperature. For example, to determine at 1400°C the oxygen activity at which nickel and nickelous oxide are in equilibrium, the so-called Ni : NiO (“NNO”) buffer for oxygen, one extends a line from the point O through the point $\Delta_r G_{(\text{Ni:NiO}; 1400^\circ \text{C})}^\circ$ and reads the appropriate p_{O_2} off the far-right axis: at this temperature, NNO is $p_{\text{O}_2} \cong 2 \times 10^{-6} \text{ atm}$ ($a_{\text{O}_2} \cong 2 \times 10^{-6}$).

¹ K_{eq} is defined for isobaric conditions; hence pressure is ignored in Eqs. (2) and (3). $\Delta_r G_{(1)}^\circ$, of course, is a function of both temperature and pressure, but as Gibbs free energy is a state variable, it can be evaluated along any arbitrary path. This presentation, thus, will concentrate on (isobaric) temperature sensitivity; the analysis is extrapolated to other pressures nominally straightforwardly through evaluation of the pressure effects on enthalpy and entropy. The “nominal” caveat is related to the requirement of having good data and models for the equations of state of the phases involved.

² There are also axes corresponding to gas mixing ratios for $\text{H}_2:\text{H}_2\text{O}$ and for $\text{CO}:\text{CO}_2$, which can be used to design a controlled-oxygen-activity atmosphere – via gas-phase reaction/equilibrium – at a specified temperature; see Ref. [4].

Figure 1 Ellingham diagram as modified by Richardson and Jeffes [4]: $\Delta_r G^\circ (=RT \ln p_{\text{O}_2})$ vs. T at ambient pressure. All reference reactions are written in terms of 1 mol of oxygen; thus plotted, the relative oxidation potentials of metals and of transition metal oxides are revealed, with more negative values of $\Delta_r G^\circ$ representing a greater oxidation potential (i.e. a more stable oxide) (1 kcal = 4.184 kJ).

Another use of the Ellingham plot is determinations of phase equilibria. Consider, for example, two specimens, one of pure Ni and the other of pure Ti, both placed in a closed system along with some pure oxygen gas, but not enough to convert fully the Ti to TiO_2 or the Ni to NiO. After a long reaction time, one predicts that the thermodynamically stable state would be a rind of TiO_2 on the Ti specimen and unoxidized Ni, with the oxygen activity of the system lowered to the Ti : TiO_2 buffer. But this experiment only “works” if the two metal specimens are not touching and if the temperature is low enough that the vapor pressures for Ti and Ni are minimal. In other words, pure Ti has a significantly greater oxidation potential than pure Ni.

This analysis is consistent with describing the reference Ti–Ni–O *displacement reaction*:

where oxygen is “displaced” from bonding with Ni to bonding with Ti. In Eq. (4) $\Delta_r G_{(4)}^\circ$ is a function of T ; it can be determined directly on the Ellingham diagram: at a fixed temperature, $\Delta_r G_{(4)}^\circ$ is the (vertical) distance between the Ni : NiO and Ti : TiO_2 buffer lines (e.g. at 1400°C , $\Delta_r G_{(\text{Ti}:\text{TiO}_2)}^\circ \approx -600 \text{ kJ}/[\text{mol O}_2]$ and $\Delta_r G_{(\text{Ni}:\text{NiO})}^\circ \approx -180 \text{ kJ}/[\text{mol O}_2]$; thus, $\Delta_r G_{(4)}^\circ \approx -420 \text{ kJ}/[\text{mol O}_2]$). It is significant to note that the Ni : NiO and Ti : TiO_2 buffer lines do not cross: consistent with the Gibbs phase rule, there is no oxygen activity at which phase-pure Ti, TiO_2 , Ni, and NiO are simultaneously stable at any given temperature. Further, it would be incorrect to interpret the Ellingham diagram or reaction (4) as suggesting that rutile ($\alpha\text{-TiO}_2$) precipitating in a Ni matrix is a thermodynamically stable assemblage: in such a hypothetical system, neither a_{NiO} or a_{Ti} is unity, which is the prerequisite for such a simple interpretation.

The Ellingham diagram (Figure 1) includes, too, reactions for heterovalent cation oxides, specifically $6 \text{FeO} + \text{O}_{2(g)} = 2 \text{Fe}_3\text{O}_4$ (the wüstite–magnetite [WM] buffer) and $4 \text{Fe}_3\text{O}_4 + \text{O}_{2(g)} = 6 \text{Fe}_2\text{O}_3$ (the magnetite–hematite [MH] buffer); other versions of the diagram might include similar reactions, e.g. for the various valence oxides of Mn (critical for dry cell battery chemistry) or Sn (critical for the float-glass process, as seen below). As evidenced by the line-like topology of their respective $\Delta_r G^\circ$ curves, the thermodynamics of these oxide–oxide reactions is identical to that of the metal–metal oxide reactions.

2.2 General Redox Reactions: The Case of Solutions

The comment concerning the non-stability of an Ni– TiO_2 composite and the parenthetical caveat about the Ni–Ti– $\text{O}_{2(g)}$ thought experiment, both presented above,

are an admonition: care must be exercised in applying the Ellingham diagram to redox problems when one is considering solutions, e.g. oxidation of metal alloys and/or redox conditions in multicomponent oxides like glasses or glassmelts. As the activities of either products or reactants shift away from unity, the Gibbs free energy driving potential is changed. This is accounted for through use of the activity quotient:

$$\Delta_r G_{(1)}(T) = \Delta_r G_{(1)}^\circ(T) + RT \ln \left(\frac{\prod_i a_i^{n_i} \text{ products}}{\prod_i a_i^{n_i} \text{ reactants}} \right), \quad (5)$$

where $\prod_i a_i^{n_i}$ are the products of the relevant activities, each raised to its respective stoichiometric coefficient (n_i). The correction term in Eq. (5) is a linear function of temperature and additionally is equal to zero at $T = 0 \text{ K}$. Given that $\Delta_r G_{(1)}^\circ(T)$ is effectively a straight line, one recognizes that, on the Ellingham diagram, the activity-quotient term simply rotates the standard-reaction free energy function about its intercept on the ordinate (i.e. about $\Delta_r H_{(1)}^\circ$ at 0 K). As different metal–metal oxide buffer lines rotate because of the activity effect, one discovers redox couples that are “unexpected,” i.e. electron exchanges reducing what are considered more stable oxides and oxidizing what are considered more noble metals.

A useful example is the redox reaction occurring in the float process for soda-lime-silica flat glass (“NCS,” which includes small amounts of Al_2O_3 and/or MgO). The original invention by Pilkington, Ltd., seemed straightforward enough: float glassmelt as a continuous ribbon on a bath of liquid metal ([5], Chapter 1.4). The metal for the float bath had six technical prerequisites: (i) an appropriate temperature range of liquid stability ($T_m < 600^\circ\text{C}$; $T_b > 1050^\circ\text{C}$), (ii) a low vapor pressure at the high- T condition ($p_i \sim 10^{-7} \text{ atm}$ at 1050°C), (iii) a density much exceeding that of NCS ($\rho_{\text{NCS};1050^\circ\text{C}} \sim 2.5 \text{ g/cm}^3$), (iv) distinct nobility relative to the metals composing the oxides of the NCS glassmelt (i.e. a siderophile element), (v) ease of environmental oxidation control, and (vi) low toxicity. Molten tin was the obvious choice, particularly when economic considerations were added to the technical ones. The process development was challenging because of the reaction between the liquid NCS and the liquid Sn. Pilkington [5] did not consider the reaction problem from the perspective of redox thermodynamics, but the redox understanding is actually crucial [6].

At its original contact with the liquid-Sn bath at $T \approx 1050^\circ\text{C}$, the NCS glassmelt contains very little – to first order, none – of the tin oxides SnO and SnO_2 ; similarly, the high-purity Sn float bath contains very little Na, Ca, or Si metal. But consider the reaction of Sn to stannous oxide in the context of the float reaction,

i.e. $2 \text{Sn}_{(l)} + \text{O}_{2(g)} = 2 \text{SnO}_{(l)}$. Not shown in Figure 1, the reference-reaction $\Delta_r G_{(\text{Sn}:\text{SnO})}^\circ(T)$ line is very close to the one for $\text{Fe}:\text{FeO}$ (Figure 2). Application of Eq. (5) gives

$$\Delta_r G_{(\text{Sn}:\text{SnO})}(T) = \Delta_r G_{(\text{Sn}:\text{SnO})}^\circ(T) + RT \ln \left(\frac{a_{\text{SnO}}^2}{a_{\text{Sn}}^2 p_{\text{O}_2}} \right). \quad (6)$$

At the glassmelt/liquid-Sn interface, at the initial contact of the glassmelt with the float medium, $a_{\text{Sn}} \cong 1$ and p_{O_2} is set by the forming-gas ($\text{H}_2:\text{N}_2$) atmosphere that is sustained in the float-bath chamber ($\sim 10^{-14}$ atm at 1050°C ; this is also the activity of oxygen in the liquid tin). As noted above, however, a_{SnO} in the glassmelt is essentially zero. As a consequence, the activity-quotient term in Eq. (6) is negative, and strongly so, $\Delta_r G_{(\text{Sn}:\text{SnO})}(T)$ is a line strongly rotated clockwise from that characterizing $\Delta_r G_{(\text{Sn}:\text{SnO})}^\circ(T)$ (Figure 2). Continuing, one can consider the $\text{Na}:\text{Na}_2\text{O}$ equilibrium for the float situation ($4 \text{Na}_{(l)} + \text{O}_{2(g)} = 2 \text{Na}_2\text{O}_{(l)}$):

$$\Delta_r G_{(\text{Na}:\text{Na}_2\text{O})}(T) = \Delta_r G_{(\text{Na}:\text{Na}_2\text{O})}^\circ(T) + RT \ln \left(\frac{a_{\text{Na}_2\text{O}}^2}{a_{\text{Na}}^4 p_{\text{O}_2}} \right). \quad (7)$$

At the glassmelt/liquid-Sn interface, $a_{\text{Na}_2\text{O}}$ is initially that of the glassmelt ($\sim 10^{-1}$), p_{O_2} is again that of the forming-gas atmosphere, but a_{Na} in the liquid Sn is vanishingly small. As a consequence, $\Delta_r G_{(\text{Na}:\text{Na}_2\text{O})}(T)$ is a line strongly rotated counterclockwise from the reference

$\Delta_r G_{(\text{Na}:\text{Na}_2\text{O})}^\circ(T)$. A similar analysis can be done for $\text{Si}:\text{SiO}_2$: $a_{\text{Si}} \rightarrow 0$ in the liquid Sn, and so the reference-reaction curve rotates counterclockwise. As illustrated in Figure 2, the $\Delta_r G_{(i)}(T)$ lines thus cross: the result is a large driving potential for Sn from the float bath to be oxidized (and added to the glassmelt ribbon) in a coupled reaction with SiO_2 and Na_2O from the glassmelt, which are reduced (and added to the liquid-metal float bath). The magnitude of the $\Delta_r G$ driving potentials for these redox couples is that of an isothermal vector from the $\Delta_r G_{(\text{Sn}:\text{SnO})}(T)$ line to either of the $\Delta_r G_{(\text{Na}:\text{Na}_2\text{O})}(T)$ or $\Delta_r G_{(\text{Si}:\text{SiO}_2)}(T)$ lines.

The activity effect illustrated in Figure 2 is important to understand, too, for any metal crucible-glassmelt reaction, including the incorporation of ionic platinum into a glassmelt through a redox couple of Pt with silica ($\pm$ less stable oxide components of the glassmelt) (e.g. [7]). The kinetics of such a reaction will be discussed below, including its implications for the chemical morphology and performance of float-processed flat glass.

A clear ramification of the thermodynamics presented here is that design of any melting and delivery process in glass manufacturing strongly depends on understanding the activity-composition relationships both in glassmelts and in the metal or ceramic materials with which they come in contact. Unfortunately, this is not straightforward: silicate melts are distinctly complex solutions (Chapter 5.3); metallic melts can be similarly complex, particularly those involving alloying with the group 14 metalloid elements, which include Sn and Si and are prominent in the float process. Silicate melt solutions

Figure 2 Ellingham diagram (after [6]) for several oxides in the float-glass reaction, for reference conditions ($\Delta_r G^\circ$; solid lines), and for the (non-reference) conditions characteristic of the liquid-Sn/glassmelt interface ($\Delta_r G$; broken lines). The curved arrows indicate the direction of rotation of the $\Delta_r G^\circ$ lines according to Eqs. (5)–(7). Because of the thermodynamics of solution formation, there is an extremely large driving potential for the reduction of components in the glassmelt (e.g. Na^+ and Si^{4+}) and the related oxidation of the liquid-Sn float medium.

are often described via polymerization (e.g. [8]) or quasi-chemical models (e.g. [9], Chapter 5.3). The latter consider silicate melts as solutions of discrete, distinctly ordered multi-ion units and are the basis for automated calculation of relatively simple systems with two or three oxide components, as, for instance, made by the calculator FactSageTM (Facility for the Analysis of Chemical Thermodynamics, Center for Research in Computational Thermodynamics, École Polytechnique de Montréal, Canada, and GTT-Technologies, Herzogenrath, Germany; <http://www.factsage.com>.) Intriguingly, complex multicomponent natural silicate melts are well modeled as regular solutions (i.e. with an ideal entropy of solution and usually a nonzero enthalpy of solution) if the appropriate units are selected as components, e.g. Fe_2SiO_4 and Mg_2SiO_4 entities instead of FeO and MgO , CaSiO_3 instead of CaO , etc. This is the approach of the quasi-chemical thermodynamic calculator MELTS and its derivatives ([10], OFM Research, Inc., Seattle, WA, USA; <http://melts.ofm-research.org/index.html>).

3 Oxidation/Reduction Kinetics

The kinetics of redox reactions in silicate melts and glasses is complicated by two physical factors. (i) The “equilibrium” structure of a glass or glassmelt depends on the valence states of the component ions (e.g. [11], Chapter 2.4); as such, redox reactions are accompanied by structural relaxations that have a direct effect on ion mobility. (ii) For transition metal cations, particularly, but also ionized metalloids such as S and Si, the incorporation of heterovalent ions affects the electronic transference number such that, for a broad range of temperatures, the electrical conductivity of a glass or glassmelt, although decidedly modest (Chapter 4.2), is effected almost exclusively by electronic species, namely, electrons in the conduction band and/or electron holes in the valence band. In condensed matter kinetics, this feature is described as the “semiconductor condition” (e.g. [1], p. 81): for electronic species, the product of concentration and mobility, that is, the transport coefficient, outstrips that of any of the ions; the result is that the fluxes of ions are all decoupled, one from another. The combination of the two effects allows for curious, sometimes surprising reaction morphologies or textures.

When a system is subjected to a differential in thermodynamic potentials that moves it out of equilibrium, the only “rule” in kinetics is that it must evolve in a manner that lowers its Gibbs free energy. There is no requirement that the system achieves a new stable equilibrium; metastable states are possible – and likely – as are discrete transient morphologies for systems continuing to evolve

as a differential potential persists. Applied to the ionic systems considered here, an additional caveat is that near-atomic-scale charge neutrality must be preserved. The situation would be more complex if glass-ceramic materials were considered because the metastability of the crystalline phase(s) would require an additional constraint on ionic flux.

The kinetics of redox reactions will be considered from two end-member perspectives.

(i) *Open systems* are where a glass or glassmelt reacts with the external environment in the process of reaching equilibrium with it through far-beyond-atomic-scale electrochemical diffusion; these situations cover both manufacturing (e.g. in the float-glass process, the continuing reaction between the liquid-metal float bath and the glassmelt ribbon) and application (e.g. oxidation of glasses originally manufactured in reducing situations but subjected to persistent use at ambient conditions characterized by a high chemical potential of oxygen).

(ii) *Closed systems* are where redox potentials are created within the glassmelt solely by the quenching process. The reactions are then local: electronic transfer associated with redox and the related structural relaxation occurs at the near-atomic scale. Closed-system understanding is important in the control of color, is put to use in glassmelt fining, and addresses manufacturing problems caused by glassmelt–crucible reactions.

4 Open-System Redox Dynamics

Consider an FeO-bearing aluminosilicate melt subjected to an environment in which the majority of Fe^{2+} is not stable. This situation happens frequently in nature with basaltic magma, an aluminosilicate melt whose nine main oxide components include the transition metal oxides FeO , MnO , and TiO_2 . In the partially molten upper mantle of Earth, redox equilibrium is originally achieved at conditions that can be taken as $T \sim 1250^\circ\text{C}$ and $p_{\text{O}_2} \approx 10^{-8}$ atm, giving a $\text{Fe}^{3+}/(\text{Fe}^{2+} + \text{Fe}^{3+})$ of ~ 0.1 . Upon eruption, the basalt is very quickly brought to ambient conditions with a $p_{\text{O}_2} = 0.21$ atm that of course persists; consequently, the basaltic glass formed in the eruption oxidizes with time, i.e. with continued exposure to the ambient environment. Ignoring convection, this oxidation must proceed by chemical diffusion, but the issue then is to determine which species are migrating.

4.1 The Phenomenology of Open-System Oxidation

The open-system oxidation problem, specifically where the valence of iron and its impact on structure of the glass

Figure 3 Kinetic modes for the oxidation of a Fe^{2+} -rich aluminosilicate glass or melt, drawn as having the external environment being that of air ($p_{\text{O}_2} = 0.21 \text{ atm}$) [12]. Three independent “modes” – I, II, and III – are illustrated.

or melt are the redox response, is presented phenomenologically in Figure 3 [12]. Three distinct dynamic responses – “modes” – to the oxidation potential are distinguished: one involving the chemical-diffusion flux of molecular O_2 (j_{O_2} ; mode I) and two others involving ionic diffusion, mode II for anion diffusion/flux, $j_{\text{O}^{2-}}$, and mode III for cation diffusion/flux, $j_{\text{M}^{2+}}$. The three modes occur simultaneously at mutually independent rates: the mode that dominates the redox kinetics is the one with the fastest initial response, i.e. that allows the internal reaction front to migrate from the free surface most rapidly. The dominant mode does not necessarily lead to the lowest Gibbs free energy state for the glass or glassmelt. This feature moves the drawing a bit away from simple phenomenology: Fe^{2+} has its primary role in a silicate glass or glassmelt as a network modifier; as the $\text{Fe}^{3+}/\text{Fe}^{2+}$ ratio increases with oxidation, Fe^{3+} more and more fills a network-former role ([11], p. 351). The internal reaction front, then, is that location where the oxygen activity becomes sufficiently high that the structural change occurs. With the molecular change, the mobility of atoms and of ions changes also.

For broad ranges of temperature and iron content (temperature as low as 800°C with a total $\text{Fe}^{2+} + \text{Fe}^{3+}$ content $\sim 10^{-2}$ at %), mode III dominates the oxidation dynamics of aluminosilicate melts and glasses [12]. Divalent network-modifying cations stream to the free surface where they react with environmental oxygen to produce (with sufficient concentration and thermal energy and/or

time) crystalline thin films of SiO_2 -free, single-cation oxides or multiple-cation oxide solid solutions or compounds such as spinel. The outward flux of cations is charge-compensated by a counterflux of electron holes, j_{h^*} . As for h^* , it is an electronic defect having a single positive charge, which is denoted by the superscript dot; the creation of the electron holes near the free surface is the source of the electrons necessary for the ionization of oxygen that is required to form the crystalline surface oxides.³ The glass or glassmelt is oxidized internally, at the internal reaction front *not* by the addition of oxygen but rather by the removal of cations, i.e. the O^{2-} -to-cation ratio does increase, but by the removal of cations. The kinetics overall are rate limited by the diffusion of divalent network-modifying cations: the distance to the redox front from the free surface, $\Delta\xi$, follows parabolic kinetics, i.e.

$$(\Delta\xi)^2 = 2k'_p t; \quad k'_p \propto X_{\text{M}^{2+}} \bar{D}_{\text{M}^{2+}} \frac{\Delta_r G}{RT}, \quad (8)$$

where k'_p is the parabolic reaction-rate constant, $X_{\text{M}^{2+}}$ is the mole fraction (concentration) of the mobile divalent network-modifying cations in the region between the free surface and the internal oxidation front (i.e. across $\Delta\xi$), and $\bar{D}_{\text{M}^{2+}}$ is the average diffusion coefficient for the divalent cations in the oxidized region (cf. [1], p. 172). As emphasized by Eq. (8), the kinetics of a diffusion-rate-limited reaction is a product of (i) the mobile-species concentration with (ii) the species mobility and with (iii) the normalized (to RT) driving potential of the reaction. An average diffusion coefficient is cited because the mobility of an ion should generally be affected by the oxygen activity (see below), which, of course, varies across thickness $\Delta\xi$.

Mode III oxidation dynamics in aluminosilicate glasses and glassmelts have a direct parallel in the dynamics of oxidation of crystalline oxides and silicates. In the crystalline state, decoupled cation fluxes occur against an immobile O^{2-} sublattice since the transport coefficient for oxygen anions is orders of magnitude smaller than that of many of the cation species, Si^{4+} being one of the obvious exceptions ([1], p. 171). Oxidation of glasses and glassmelts suggests that cation diffusion, specifically that of network-modifying cations, occurs against the relative immobility of the ionic species involved in the network.

³ Mode III kinetic response is *prima facie* evidence that the semiconductor condition holds for iron-oxide-bearing glasses and glassmelts. FeO-bearing, multicomponent crystalline oxides/silicates or glassmelts/glasses are broadly demonstrated to be *p*-type (i.e. h^* ; the *p* stands for positive) semiconductors: over a broad range of temperature and of FeO composition, the conductivity of the material occurs via electron transfer from Fe^{2+} to Fe^{3+} within the valence band of the material, that is, charge transfer occurs by the motion of vacant electron states (“holes”) within the otherwise filled valence band.

Because the dynamics in the crystalline state are effected by the motions of point defects, the similar dynamics in glassmelts and glasses suggests a parallel to point defects that are operative in the amorphous state. As consequence, one can couple a phenomenological description of the kinetics with a qualitative understanding of the dynamics that identifies defects and their reaction-impelled motion in the amorphous state.

Kinetically, phenomenologically, mode III can be understood by evaluating the two active compensating fluxes, $j_{M^{2+}}$ and $j_{h^{\cdot}}$, using Fick's first law, i.e.

$$\begin{aligned} j_{M^{2+}} &= \frac{-c_{M^{2+}} D_{M^{2+}}}{RT} \frac{d\eta_{M^{2+}}}{d\xi} \\ &= \frac{-c_{M^{2+}} D_{M^{2+}}}{RT} \left(\frac{d\mu_{M^{2+}}}{d\xi} + 2F \frac{d\varphi}{d\xi} \right) \end{aligned} \quad (9)$$

and

$$j_{h^{\cdot}} = \frac{-c_{h^{\cdot}} D_{h^{\cdot}}}{RT} \frac{d\eta_{h^{\cdot}}}{d\xi} = \frac{-c_{h^{\cdot}} D_{h^{\cdot}}}{RT} \left(\frac{d\mu_{h^{\cdot}}}{d\xi} + F \frac{d\varphi}{d\xi} \right). \quad (10)$$

With Eqs. (9) and (10), Fick's first law is depicted as modified by Einstein, i.e. the driving force for chemical diffusion is not a gradient in concentration, but rather the gradient in chemical potential or, for ionic solids and liquids, the gradient in electrochemical potential ([1], p. 63). In these equations, c_i is the concentration, η_i the electrochemical potential, and μ_i the chemical potential each of the species i , whereas φ is the electrical potential and F is Faraday's constant (96 485 J/mol/V). The continuity condition is the requirement for charge neutrality:

$$\sum_i z_i j_i = 0 = 2j_{M^{2+}} + j_{h^{\cdot}} \quad \text{or} \quad 2j_{M^{2+}} = -j_{h^{\cdot}}, \quad (11)$$

where z_i is valence. For mode III to be operational, $(c_{h^{\cdot}} D_{h^{\cdot}})$ is much greater than $(c_{M^{2+}} D_{M^{2+}})$; on this basis, one finds that $d\eta_{h^{\cdot}} = 0$ when substituting Eqs. (9) and (10) into Eq. (11): hence, one cannot sustain an electrochemical potential gradient for the electron holes, which is the definition of the semiconductor condition introduced earlier. Concentrating on the divalent-cation flux (Eq. 9), one sees that the chemical potential gradient of an ion species is expressed, specifically $d\mu_{M^{2+}}/d\xi$, which is difficult to control in experiments or in production, as was noted in the Introduction. Knowing how neutral species are formed by reaction of ions with electrons (e.g. $M^{2+} = M + 2h^{\cdot}$) and oxide components by the reaction of metal with oxygen ($M + \frac{1}{2}O_{2(g)} = MO$), one can transform Eq. (9) into a description of mode III oxidation [12]:

$$j_{M^{2+}} = \frac{+c_{M^{2+}} D_{M^{2+}}}{2RT} \frac{d\mu_{O_2}}{d\xi}. \quad (12)$$

This equation is of fundamental importance in understanding mode III oxidation: it proclaims that a chemical potential gradient of oxygen can have, as its primary response, a flux of cations; oxidation needs not require a flux of atomic, molecular, or ionic oxygen.

The operation of mode III oxidation has been demonstrated with ion (Rutherford) backscattering spectroscopy (RBS) (e.g. [12]). These experiments revealed the existence of surface oxide films, which are not represented in Figure 3, whose thickness increases with reaction time, and also the rather sharp boundary of the oxidation front that moves inward. Both the growth of the crystalline surface film (or of divalent-cation concentration in its absence) and that of the divalent-cation-depleted oxidized glass zone follows parabolic kinetics. Further, the rate of growth of $\Delta\xi$ matches well the tracer-diffusion rate for divalent network-modifying cations for the composition/structure of the oxidized glass, which is orders of magnitude faster than that of oxygen tracer diffusion whether by atoms, molecules, or ions [12, 13].

Whereas mode III response is robust, the morphology/texture of the reaction is sensitive to the thermodynamic conditions. A FeO-bearing CaO–MgO aluminosilicate glass ("Fe-CMAS"; no alkali oxides) oxidized in air near its glass transition temperature, for example, results in nm-scale crystalline ferrite ($MgFe_2O_4$) being precipitated at the internal oxidation front; these precipitates exist in a substantially iron-depleted, oxidized glass. In contrast, a basaltic glass (prepared from remelted basalt rock), similar in polymerization to the Fe-CMAS glass but containing ~4.1 mol % of total alkali oxides ($Na_2O + K_2O$), experiences no internal precipitation of ferrite. "Stabilization" of Fe^{3+} as a network former in the oxidized glass occurs instead through incorporation of alkali ions, particularly Na^+ , which had diffused from significant depth in the specimen to the internal oxidation front [12]. For a basaltic liquid subjected to an air environment, however, mode III oxidation still occurs, but the internal interface is the place where the oxygen activity is such that ferrite (Fe_3O_4) becomes a liquidus phase for the temperature of the experiment: the structural changes in the melt wrought by the loss of divalent cations to the free surface changes the liquidus equilibrium (the phase diagram "evolves"): the liquid thus gets supercooled isothermally [13].

There are variations on the theme of reaction modes presented in Figure 3; these depend on the overall chemistry of the glassmelt or glass and/or temperature. As the alkali oxide content of a glassmelt increases, particularly relative to the content of transition metal oxides, the transport coefficient of the alkali ions (particularly $Na^+ \pm K^+$) can, for example, exceed that of the electronic species. Mode III can remain the dominant mechanism, but

the compensating flux becomes that of alkali ions: the oxidized glassmelt changes from an electronic to an ionic or a mixed conductor (e.g. [14]). Again with a sufficient content of network-modifying alkali or alkaline earth oxides, the dynamics can evolve to mode II as temperature increases, with a compensating flux provided by cations instead of by $h^\bullet$ (e.g. [15]). The shift to mode II with increasing temperature is straightforwardly understood: the activation energy for mobility of O^{2-} is greater than that of the network-modifying cations. One consequence is that at high enough temperature the mobility of O^{2-} will exceed that of the network-modifying cations, and thus the O^{2-} transport coefficient becomes dominant. Molecular O_2 also sees its mobility increase rapidly with temperature [15]. A change of redox dynamics to mode I is unlikely for most multicomponent silicates, however, due to the limited solubility of the gas keeping the O_2 transport coefficient relatively small.

4.2 A Structural Perspective on Open-System Oxidation Dynamics

As noted above, mode III oxidation of glassmelts and glasses is similar to that observed in crystalline oxide or silicate solid solutions. In $(Fe,Mg)O$ (magnesiowüstite) and $(Fe,Mg)_2SiO_4$ (ferromagnesian olivine), as examples, the physical manifestation of the oxygen activity is the coupled concentrations of negatively charged vacancies on the divalent-cation sublattice, which are denoted by $V''_{M^{2+}}$ (NB. the subscript denotes the sublattice and the superscript charge – a prime is a negative charge; here there are two of them), and electron holes, which physically are Fe^{3+} present on the divalent-cation sublattice ($h^\bullet \equiv Fe^\bullet_{M^{2+}}$). The concentrations are coupled by the requirement of charge neutrality, specifically $[h^\bullet] \cong 2[V''_{M^{2+}}]$, where the brackets denote the number of defects per molecule on the lattice, a unitless concentration. As the oxygen activity increases, the concentration of both defects increases: $[h^\bullet], [V''_{M^{2+}}] \propto p_{O_2}^m$ where $m \sim 1/6$ ([1], p. 171). In the oxidation of these (and similar) Fe^{2+} -bearing crystalline compounds, then the hole and vacancy concentrations are higher at the free surface and lower in the interior. Holes and vacancies thus flux inward, whereas the geometric requirement that a vacancy exchange with an ion on its sublattice imposes a divalent-cation flux outward: mode III. It is important to note that the motion of $h^\bullet$ does not require the diffusion of Fe^{3+} ions; rather only the electron is moved from one iron ion to another, which is a much faster and lower-energy process. Nevertheless, the defect $Fe^\bullet_{M^{2+}}$ causes a local distortion in the crystal structure, a “small polaron,” which tracks with the motion of the electron hole; the diffusion process is described as polaron

hopping and is characterized by a Boltzmann statistics that is similar to that of ionic diffusion.

Of course glassmelts and glasses have neither a lattice nor sublattices. But they do have an atomic structure, and mode III oxidation response of network-modifying cation motion against a relatively immobile aluminosilicate network evokes parallels to point-defect phenomena. The structure of amorphous silicates is described statistically: bond lengths and bond angles have distributions. Defects, then, can be viewed as extraordinary bond lengths and angles, a perspective originally championed by Schaeffer [16]. Based on dynamical similarities between the amorphous and crystalline states, one may anticipate the creation of such defects at equilibrium concentrations of a part per thousand, atomic, or less. The defect concentrations, being functions of both temperature and chemical potential(s), can be characterized through chemical equilibria. One effective approach to this end is an application of the polymerization model of Hess [8].

The Hess model evaluates polymerization of amorphous silicates by paying particular attention to the bonding environments of oxygen anions: structural elements in reactions are described by having the bonds to each O^{2-} characterized by a summed Pauling bond strength (electrostatic valence) of two; these elements are then used to write reactions that are balanced both in matter and in charge. For example, in the case of the oxidation of a glass or glassmelt at its free surface, network-modifier Fe^{2+} reacts with atmospheric oxygen to create network-modifier Fe^{3+} ; in Hess notation,

In reaction (13), SiOSi represents a bridging oxygen, $2 \text{ SiOFe}_{0.5}$ represents a network-modifier Fe^{2+} , which provides one positive charge to each of two O^{2-} , and $3 \text{ SiOFe}_{0.33}$ represents a network-modifier Fe^{3+} , which is the manifestation of an electron hole, or small polaron, in the amorphous structure. By inspection, one sees that reaction (13) is atomically balanced. The reaction is charge-balanced as well: two Fe^{2+} cations have provided one electron each to ionize the neutral oxygen atom, which is then bonded to the amorphous silicate. The reaction is depicted schematically in Figure 4a, whose part (1) represents the left side of the equilibrium and part (2) the right, Fe^{2+} being represented by the generic M. One easily imagines that the bonding of the oxidized iron ($Fe^{3+} \equiv M-h^\bullet$ in the figure) to three O^{2-} anions instead of Fe^{2+} to two anions distorts locally the structure of the glassmelt/glass; in Figure 4, this feature is depicted as a polyhedral void. Nevertheless, one understands that as the electron holes migrate inward, the distortion travels with them and divalent cations are displaced in the opposite direction (Figure 4b): in the kinetic response, the

distortion acts effectively as a “vacancy” in the amorphous structure. As suggested by Greaves [17], Figure 4b additionally assumes a percolative nature for the spatial distribution of network-modifying oxide components in the amorphous state; such an interpretation is consistent with the redox reaction textures of sufficiently depolymerized melts/glasses [11, p. 317].

One can infer from reaction (13) that the oxidation reaction is depolymerizing because the bridging oxygen unit Si–O–Si is consumed. This is counter to experience according to which oxidized glassmelts increase in polymerization and so in viscosity. But it must be emphasized that reaction (13) is actually a “half reaction,” that is, the overall oxidation reaction is the sum of two half reactions, one at/near the free surface (depicted in Figure 4a) and the other at the internal reaction front, the two half reactions mediated and rate limited by chemical diffusion ([1], p. 104). As described above for some non-alkali oxide-bearing glasses, the reaction at a temperature near the glass transition causes precipitation of nm-scale ferrite at the internal interface. The simplified version of this half reaction, in Hess notation, is

where M here is either Mg^{2+} or Fe^{2+} (i.e. the magnesioferrite–magnetite solid solution; the subscript “Sp” standing for crystalline spinel). Here one sees the formation of four bridging oxygens as three network-modifying cations are extracted from the solution (plus the requisite amount of O^{2-}) to form the crystalline ferrite. In glasses with alkali oxides, Fe^{3+} tends to have a network-former status, charge-compensated by a localized alkali ion that no longer fulfills a network-modifier role. Taking Na^+ as the alkali species, one simplifies in Hess notation this half reaction as

where NaFeO_2 represents the network-forming Fe^{3+} [8]; six bridging oxygens are formed in the consumption of eight nonbridging oxygens. A summation of reaction

Figure 4 Schematic illustration of small polaron dynamics in silicate glassmelts and glasses [13], with structural units based on the melt polymerization model of Hess [8]. M is a divalent network-modifying cation; M–h[•] is a trivalent network-modifying cation. (a) Formation of a small polaron via oxidation (cf. reaction (13)): (1) unreacted glass/glassmelt and (2) formation of a polaron as two divalent network modifiers become trivalent network modifiers as atmospheric oxygen accepts two electrons and bonds into the glass/glassmelt as O^{2-} . The structural distortion so created follows the migration of the h[•]. Note also the consumption of a bridging oxygen (Si–O–Si): this near-surface (half) reaction is depolymerizing. (b) Migration of a small polaron, and the associated (counter) motion of the network-modifying cation, in a transition metal-bearing silicate glass/glassmelt.

(13) with either reaction (14a) or (14b) illustrates a definite net increase in polymerization for the oxidized glass/glassmelt.

The simplification in reactions (13) and (14) is that each half reaction must have as a product the mobile species that “communicate” the oxidation potential between the external and internal interfaces. The free-surface reaction, reaction (13), clearly produces $2h^*$ ($\equiv 6 \text{ SiOFe}_{0.33}$), which diffuse inward; a more complete description of reaction (14a and b) at the internal interface must include the fact that the structural relaxation that results in precipitation of ferrite or in incorporation of Fe^{3+} as an alkali-ion-compensated network former must also “release” divalent network modifiers to diffuse toward the free surface. These more complete reactions are described in [12] and in the references cited there.

4.3 Open-System Reduction and the Float-Glass Reaction

Under some circumstances, dynamic reduction can be understood as the mirror image of the oxidation process. Specifically, O^{2-} is chemically ablated (i.e. by reaction with neutral species in the atmosphere) from the free

surface in a half reaction that consumes h^* ; the reaction both decreases the activity of h^* and increases the activity of divalent-cation oxides at the free surface, impelling outward diffusion of h^* and inward diffusion of M^{2+} network-modifying cations. These dynamics are essentially the reverse of reaction (13) and of Figure 4a, i.e. consider the compound figure in the order (2) $\rightarrow$ (1). Structural relaxation of the glassmelt/glass occurs at an internal interface, one that shifts ever deeper, following parabolic kinetics. Depending upon the thermodynamic conditions, the internal reaction can yield, too, precipitation of nm-scale precipitates of metal ([11], p. 326).

The foundation of the float-glass reaction, from the perspective of the glassmelt ribbon, is dynamic reduction that is accompanied by solution formation; the metallic float medium experiences oxidation and solution formation, but this side of the reaction is not rate limiting and so is ignored here. The thermodynamics was articulated in Section 2.2 and illustrated in Figure 2. At the molten tin/glassmelt interface, tin is oxidized through electron donation to cations in the silicate, which are reduced: Sn^{2+} then is incorporated into the glassmelt, and metallic Na (particularly), Si, Fe (a minor component of NCS glass), and Ca are added in various amounts to the tin bath. The reaction texture is telling (Figure 5a).

Figure 5 Open-system redox dynamics in the NCS-on-Sn float-glass process [6]. (a) Schematic summary of chemical observations of ionic Sn and Fe in the near-float-surface region ($\sim 50\text{--}100 \mu\text{m}$) of the glassmelt ribbon. Ionic Sn is concentrated in the first 500 nm and then assumes a Fickian compositional profile, but one punctuated with an anomalous buried hump. Ionic Fe is depleted in the region of Sn diffusion, but shows an anomalous maximum near the depth limit of Sn penetration. Sn^{2+} is the dominant Sn oxidation state at/near the surface, giving way to Sn^{4+} at the position of the Sn hump (see top of schematic). The concentration humps for Sn and for Fe are evidence of two internal redox couples effecting local structural change in the glassmelt. (b) Schematic of fluxes (with senses shown) and internal reaction fronts (ξ' and ξ'') active in the glassmelt/float-metal reaction, consistent both with the chemical profile presented in (a) and with an understanding of dynamic reduction effected by cation diffusion.

(a)

(b)

Employing a variety of analytical techniques, surface-science studies of the float-bath side of the glassmelt ribbon reveal Fick's second law diffusion profile for ionic Sn extending into the silicate. This profile, however, is punctuated by an anomalous Sn-concentration hump, which is distinctly inconsistent with simple diffusion-effected solution formation [6]. Near the end of ionic Sn penetration, one also finds an anomalous hump of the ionic Fe concentration. These humps are unequivocal evidence of reaction-effected changes in the internal atomic structure of the glassmelt, both of which are related to redox dynamics. Referring to the schematic geometry depicted in Figure 5b, one sees that the Sn hump corresponds to a location where Sn^{2+} , a reasonably mobile network modifier, is oxidized to Sn^{4+} , which, if still too large a cation to be a network former, will have a notably diminished mobility compared with Sn^{2+} in the glassmelt. The location of this internal interface ($\xi = \xi'$ in Figure 5b) corresponds to the position where the activity of SnO is sufficiently high to drive a redox couple where 2h^+ are consumed in the creation of Sn^{4+} . This reaction creates a "sink" for h^+ at ξ' , which is dealt with by a flux of h^+ emanating from the deeper interface ξ'' , the site of the internal reduction reaction. At ξ'' , reaction (14b) is driven from the right to the left, i.e. Na^+ -compensated network-former Fe^{3+} is reduced to a combination of network-modifier Fe^{3+} ($\equiv \text{h}^+$), network-modifier Fe^{2+} , and network-modifier Na^+ . The physics of the reactions and the nature of the fluxes depicted in Figure 5b are justified in Ref. [6]. As evidence in its favor, we have employed this analysis to demonstrate distinct control of the kinetics of the float reaction by (i) doping the glassmelt with additional electron acceptors (Fe^{3+}), (ii) alloying strongly the float medium (i.e. to lower the activity of Sn), and (iii) replacing Sn altogether in the float medium with an alloy whose oxidizable component, when fully ionized, assumes a definite network-former role within the glassmelt (e.g. Ge).

5 Closed-System (or Internal) Redox Dynamics

The other end-member dynamics are where diffusion beyond the molecular scale is not anticipated because of either (i) sluggish kinetics at low temperature or (ii) little time spent at an elevated temperature. The extreme situation of this type is thermal quenching, where the thermal diffusivity and heat flux outstrip the transport coefficient of any atomic/ionic component of the system. In such situations, the composition of the glassmelt/glass cannot change, but the redox potentials can because of the relative temperature effects on the activity coefficients of the components.

This evolution of the redox potentials is illustrated with an Ellingham-diagram analysis in Figure 6, which compares open- and closed-system thermodynamics for an iron-oxide-bearing calcium-magnesium aluminosilicate melt that has been driven to equilibrium with a very low oxygen activity [18]. The condition where $T = 1400^\circ\text{C}$ and the oxygen activity is controlled and sustained at 6.4×10^{-15} (i.e. an ambient-pressure fugacity of $f_{\text{O}_2} = p_{\text{O}_2} = 6.4 \times 10^{-15} \text{ atm}$) is noted in Figure 6a as the center of the small circle, nominally at the right center of the diagram, whose ordinate is $-460 \text{ kJ}/(\text{mol O}_2)$. This condition is highly reducing; the oxygen activity is four and a half order of magnitude below that for the reaction between metallic iron and the mineral wüstite ("IW-4.5") for this temperature. In this example, the oxygen activity is created and sustained by dynamic mixing and reaction of $\text{CO}_{(\text{g})}$ and $\text{CO}_{2(\text{g})}$ at a ratio of 750 : 1; thus, beyond setting the oxygen activity, the glassmelt at equilibrium must incorporate carbon oxides in forms that include physically dissolved molecular species (i.e. present in the free volume of the melt) as well as chemically dissolved ionic/covalent species (i.e. incorporated into the structure of the glassmelt as, e.g. carbonate, carbonyl, or even

Figure 6 Thermodynamic analysis associated with open-system reduction and closed-system (internal-redox-couple) quenching [18]. (a) Ellingham diagram drawn to demonstrate equilibration of an iron-oxide-bearing calcium-magnesium aluminosilicate glassmelt held at 1400°C and maintained at an oxygen activity (fugacity, f_{O_2}) of $6.4 \times 10^{-15} \text{ atm}$. In this example, the low-oxygen-fugacity environment was set by dynamic mixing of carbon monoxide and carbon dioxide at a ratio of $\text{CO} : \text{CO}_2 = 750 : 1$; at 1400°C , this produces an f_{O_2} that is four and a half order of magnitude lower than the iron-wüstite buffer, i.e. "IW-4.5." Equilibrium requires that each and all of the $\Delta_r G^\circ$ curves (solid lines) must rotate – that is, all activities are adjusted (cf. Eq. (4)) – such that all $\Delta_r G$ curves (dashed lines) converge at the thermodynamic conditions. In the figure, the only $\Delta_r G^\circ$ and $\Delta_r G$ lines presented are those involving heterovalent cations – $\text{C}^{2+,4+}$, $\text{Si}^{2+,4+}$, and $\text{Fe}^{2+,3+}$. The reaction depicted as fayalite-hematite-quartz (FHQ) is used for the Fe^{2+} – Fe^{3+} equilibrium, consistent with the solution model MELTS [10]. (b) A close-up of Ellingham "space" for quenching. From the equilibrium condition, one evaluates an effective oxygen potential (fugacity, $f_{\text{O}_2}^*$) by holding the mole fractions constant – the definition of quenching – but allowing the activity coefficients to change with temperature. The solid curve is the effective oxygen potential calculated for the FHQ reaction directly from MELTS. The dash-dot-dot curves are logical postulates based upon limited solution data for $\text{Si}^{2+,4+}$ and $\text{C}^{2+,4+}$. The divergence of the curves demonstrates that there develops a potential upon cooling to reduce C^{4+} to C^{2+} through a redox couple that oxidizes Fe^{2+} and/or Si^{2+} . The extent of these reactions in reality (in this case, causing bubbles of $\text{CO}_{(\text{g})}$ to form, C^{2+} being especially insoluble in aluminosilicate melts) depends on the thermal history, particularly the cooling rate.

carbide species). Equilibrium with the open system requires all of the component oxide $\Delta_r G(T)$ curves (lines) to converge at the aforementioned condition. Some of the Ellingham $\Delta_r G^\circ(T)$ lines rotate clockwise, some counter-clockwise. Most of the rotation is based on the activity effects of forming the glassmelt solution, although the impact of oxygen activity on curve rotation is significant.

In the analysis of quenching, one determines an “effective” oxygen activity, presented in Figure 6b as an effective fugacity, $f_{O_2}^*$, by holding mole fractions fixed but evaluating the potential based on the temperature sensitivities of the various activity coefficients ([3], p. 240). Consider the $Fe^{2+}-Fe^{3+}$ equilibrium. Because fayalite and hematite are the components representing ferrous and ferric iron, respectively, in the MELTS solution model [10], the reaction of interest is fayalite (Fa) being oxidized to hematite (Hm) plus quartz (Q): $2Fe_2SiO_4 + O_{2(g)} = 2Fe_2O_3 + 2SiO_2$ (“FHQ”). The mass-action relationship for the glassmelt is

$$\begin{aligned}\Delta_r G_{1400^\circ C} &= -460 \text{ kJ} [\text{mol } O_2]^{-1} \\ &= \Delta_r G_{T, FHQ}^\circ + RT \ln \\ &\quad \left[\frac{(\gamma_{Hm}^2 X_{Hm}^2)(\gamma_Q^2 X_Q^2)}{(\gamma_{Fa}^2 X_{Fa}^2)(f_{O_2}^*)} \right],\end{aligned}\quad (15)$$

where X_i is the mole fraction and $\gamma_i (= \gamma_i(T))$ is the activity coefficient, both of species i in the glassmelt solution, and $f_{O_2}^*$ is in units of atm (i.e. the oxygen term becomes unitless by its normalization to 1 atm). The calculation is “pinned” to the condition where equilibrium was established at 1400 °C.

As temperature is lowered, $\Delta_r G_{FHQ}^\circ$ evolves as do the γ_i ; holding the X_i fixed at their values of the original 1400 °C equilibrium allows calculation of $f_{O_2, FHQ}^*(T)$, which is shown as the FHQ* solid line in Figure 6b. The slope of FHQ* is steeper than the FHQ curve in Figure 6a. Given good solution models, similar calculations might be done for the CO/CO₂ and SiO/SiO₂ equilibria, which, unfortunately, have not been calibrated. The dash-dot-dot curves in Figure 6b are thus drawn based on inferences from the literature concerning the solubilities of the various species in an alkaline earth aluminosilicate melt. One sees that, with increased cooling, a greater and greater potential develops for the reduction of C^{4+} to C^{2+} by acceptance of electrons from Fe^{2+} and Si^{2+} . Whether the redox-exchange reaction is realized, of course, depends on the kinetics of cooling and on any subsequent thermal treatment. Since the redox exchange is accompanied by structural relaxation of the glassmelt or glass, the kinetics will be phonon assisted, again following Boltzmann statistics.

The thermodynamics described in Figure 6b can be applied to decipher a variety of phenomena encountered in glassmaking and also to understand the structure and chemistry of melts from studies of quench specimens.

Brightly colored “ruby” glasses are created by the precipitation of noble (e.g. Au) or relatively noble (e.g. Ag, Cu) colloidal metal via “striking,” i.e. driving a closed-system redox exchange by reheating a formed, often colorless glass (Chapter 6.2). In gold ruby glasses, the gold in the high-temperature glassmelt exists in ionized form ($Au^+ \pm Au^{3+}$). To produce colloidal metal, a reducing agent is added, a typical one being SnO, although oxides of Se and Te have been used historically as well [19]. The thermodynamics of striking are directly analogous to the closed-system C–Si–Fe redox couples presented in Figure 6b. Reheating and holding the glass at a temperature below its original melting/solution temperature, usually between the annealing and softening points, provokes the redox exchange $Au_2O + SnO = 2 Au + SnO_2$; the magnitude of the $\Delta_r G$ exchange potential allows the barrier to crystal nucleation to be overcome. The “soak” time of anneal is selected to effect growth of the colloidal metal crystals so as to achieve the desired color and saturation. The growth process is an Ostwald ripening. Its slowness is due to the insolubility of metal atoms in the silicate solution, since diffusion through the silicate is accomplished by ions and not by atoms ([20], p. 723).

These very same physics effect the precipitation of Pt metal inside quenched melts that are initially prepared in platinum crucibles or in Pt-lined production furnaces [7]. Platinum, too, dissolves into glassmelts as an ionic species ([20], p. 723); as a consequence, melts with as high a polymerization as practicable that are melted in a reducing atmosphere minimize the incorporation of Pt^{2+} and Pt^{4+} and so the potential for its internal reduction into metal precipitates [7].

In contrast, the solubility of platinum-group elements (PGE: Ru, Rh, Pd, Os, Ir, and Pt) in highly depolymerized, high-temperature aluminosilicate melts is of particular interest with regard to understanding the chemistry and physics of terrestrial planetary differentiation and core formation. For years, this solubility was underestimated because of the formation of PGE metal “micronuggets” within the quenched experimental charges: this metal was not understood to have precipitated as a result of a closed-system redox reaction such as described here. The correct explanation has been arrived at through clever experiments under extreme conditions (2500 °C; 2.2 GPa), whereby a highly MgO- and FeO-rich aluminosilicate melt was reacted with platinum metal in the context of containment within a graphite capsule. When the melt experienced sufficiently rapid cooling and a

sufficient cooling-rate gradient, the redox-effected precipitation of metal and of $\text{CO}_{(\text{g})}$ in the more slowly cooled regions of the charge could be observed along with the high solubility of ionic Pt and C corresponding to the experimental conditions [21]. The carbonate (or carbonyl) reduction to $\text{CO}_{(\text{g})}$ follows exactly the physics depicted in Figure 6b.

The removal of gas bubbles or “seed” by fining of glassmelts has long involved application of redox agents, particularly $\text{As}^{3+,5+}$ and $\text{Sb}^{3+,5+}$, a practice that is now less frequent owing to environmental and worker-health concerns and also, in the case of glass used as substrates for electronic displays, because of chemical incompatibilities between these group 15 metalloids and silicon- or germanium-based circuitry. The pentavalent oxides added to the glass batch are reduced to the trivalent state during melting. For many years, the release of oxygen gas by the reaction, e.g. $\text{As}_2\text{O}_5 = \text{As}_2\text{O}_3 + \text{O}_{2(\text{g})}$, was thought to facilitate the gravity-driven migration of bubbles to the free surface. Given the small amount of pentavalent oxide added to the batch, however, calculations of Stokes’ flow dynamics of bubbles so produced suggest that this reaction represents a minor contribution to fining. Rather, the re-oxidation to the pentavalent state at a lower temperature can absorb oxygen from the bubbles and thus cause them to shrink [22, 23].

Overall, the physics of fining are a convolution of the open- and closed-system cases presented above. Again, one can understand the driving potential for the trivalent-to-pentavalent oxidation reaction in a way consistent with the closed-system description of Figure 6b, but at issue is the amount of physically dissolved $\text{O}_{2(\text{g})}$ in the glassmelt. As the glassmelt cools, thermal contraction reduces the free volume of the melt; consequently, the chemical potential of the physically dissolved $\text{O}_{2(\text{g})}$ increases. Re-oxidation of the fining agent consumes some of this physically dissolved oxygen through its incorporation into the melt structure as O^{2-} and so affects locally the structure of the glassmelt. The modified glassmelt can thus accept more $\text{O}_{2(\text{g})}$ molecules from the bubble, shrinking it. This situation is similar, of course, to the surface reactions associated with an open system. Kinetic models for bubble shrinkage in the reaction so described employ a simple Fick’s second law approach but are only partially successful: despite being rate limited by diffusion of molecular oxygen, the dynamics probably has more in common with the open system as depicted as mode I in Figure 3, where the internal interface is the place where the trivalent-to-pentavalent reaction and structural relaxation occur.

Particularly in NCS glassmelts, an additional aspect of the fining process is that the Na_2O and CaO components are frequently introduced as carbonates in the batch.

Breakdown of these carbonates produces $\text{CO}_{2(\text{g})}$, which makes up a significant component of the gas bubbles to be removed in fining. Again, consistent thermodynamically with Figure 6b, redox couples between the CO_2 and the trivalent metalloid oxide component in the glassmelt oxidize the metalloid to the pentavalent state while producing $\text{CO}_{(\text{g})}$, whose transport coefficient through the glassmelt to its free surface is much, much greater than that of $\text{CO}_{2(\text{g})}$ ([24], p. 210).

6 Perspectives

The bulk properties of glasses such as color, electronic and ionic conductivity, viscosity, etc. are directly related to atomic-level structure and, thus, to ion valence. Endowing a bulk glass with specific properties via internal (closed-system) redox couples is a thermochemical design problem of broad flexibility because it makes available control of chemical activities via composition and of cooling-effected driving potentials in both post-melting and post-forming processing; optimal protocols can be identified via multivariable experimental design. More intriguing, however, are the possibilities of open-system redox in affecting/effecting electro-optical response in glass at or near the free surface. Consider, for example, a processing approach whereby the float bath is alloyed with transition element or rare earth metals so as to incorporate these in the near surface of the glassmelt via redox exchange. Depending on the initial composition of the glassmelt, the combination of redox exchange and solution formation can produce not just one specific location of a controlled local structure (like the Sn hump in conventional NCS float glass; Figure 5a) but multiple layers of such structure, i.e. redox-effected Liesegang banding. Optical interference and amplification are potential responses that can be so controlled.

Optical Basicity: Theory and Application

John A. Duffy

University of Aberdeen, Old Aberdeen, Scotland, UK

1 Introduction: The Need for a Suitable Basicity Scale for Oxide Melts

Ordinary glass is made by heating a mixture of basic oxides, Na_2O , CaO , etc. with SiO_2 . The vast range of possible compositions allows much scope for optimizing properties such as refractive index or color, mechanical strength, or high-temperature chemical reactivity. Extensive correlation studies have shown convincingly that properties of the glass or melt rely heavily on chemical composition in terms of basicity (basicity rather than acidity, because usually bases are the focused variable).

For many years, however, the quantifying of basicity was a frustrating problem. Probably the most serious limitation to progress was to disregard the fundamental difference of the O^{2-} ion compared with other monatomic anions that are usually encountered in solution chemistry. These are singly charged, but for oxygen, addition of a second electron to the already charged O^- ion is thermodynamically unfavorable. In the present context, this questions the viability of the O^{2-} species. The seriousness of this problem is illustrated by the questionable adoption of the Lux-Flood theory (a discussion of which is in [1]) together with its analogy of $p(\text{oxide})$ with pH and also by the improbable anionic counterions suggested for redox equilibria. As illustrated by many examples, redox reactions impinge greatly on molten salt chemistry. Thus, for the $\text{Fe}^{2+}/\text{Fe}^{3+}$ ion couple in the manufacture of glass, the equilibrium might be written as

Likewise, the refining action of metallurgical slags can be described by

Thermodynamic approaches to such equilibria are not straightforward. Indeed, Eq. (1) suggests that increasing melt basicity favors the lower oxidation state cation, whereas experimentally one usually observes the reverse.

There was much research effort attempting to deal with the problems, especially in view of their technological importance. Overall, the literature of the time (up to the 1970s), and meetings of professional groups, reflected notable conflict. What was needed was a chemically convincing theory with a numerical scale that would facilitate meaningful comparisons between, say, a sodium silicate, a potassium silicate, and a sodium borate melt. Trends in physical and chemical properties would then be linked directly to this *common* scale rather than to chemical constitution. Such a scale was eventually provided in 1971 with the introduction of the optical basicity theory [2].

2 Theoretical Foundation of Optical Basicity

With the concept of optical basicity, one considers an oxide glass or crystal in artificial terms as an array of its constituent cations, Na^+ , Ca^{2+} , Si^{4+} , ... and O^{2-} ions. Chemical bonding between these species, which can be described as Lewis acid–base neutralization, uses much of the negative charge on the oxygen. It is the remaining charge that chiefly causes those properties of the glass that are recognized as its basicity. Because this residual charge varies markedly with cation composition, it is the measuring of these changes in electronic charge that is at the heart of optical basicity.

To achieve this goal, probe cations are dissolved in the molten glass. They were specially chosen, so when they are coordinated by the oxygen atoms of the glass, they

Reviewers: M.D. Ingram, University of Aberdeen, Old Aberdeen, Scotland, UK

would signal fundamental features of the chemical bonding. Transition metal ions can be seen as an obvious choice because their bonding is understood in terms of molecular orbital theory (which, as the ligand field theory, had been purposefully developed for inorganic coordination chemistry during the years leading up to ~1950). Their d–d spectra, obtained using conventional UV/visible/near-infrared (optical) spectroscopy, reveal a decrease in repulsion energy between the electrons in their d-level. It is this effect that concerns the optical basicity model because, vitally, it provides a simple description of the chemical bonding between the probe ion and the oxygen atoms of the glass. For transition metal complexes, chemical bonding generally results in the d electrons experiencing greater shielding from the positive nucleus, extra to that provided by the core electrons. Consequently the d orbitals expand and the d–d repulsion decreases. It was C.K. Jørgensen who referred to this expansion as the *nephelauxetic* effect [3].

The repulsion between the d electrons is expressed as the Racah B parameter. For the free uncombined metal ion, this important energy (frequency, B_f) is known from its atomic spectrum, which is published in standard tables. When the metal ion is complexed by the ligands and the orbitals expand, B_f falls to B_{complex} . Since B_f represents 100 % ionicity, decreasing B can be taken as the introduction and increase of covalency within the bond between the ligand and metal ion. Jørgensen assigned the proportional reduction of the Racah parameter, i.e. the ratio $(B_f - B_{\text{complex}})/B_f$, to the contributions of ligand and metal ion (parameters h and k) such that

$$\frac{(B_f - B_{\text{complex}})}{B_f} = h k. \quad (3)$$

The h parameter was set at unity for the H_2O ligand in crystalline aqua complexes such as $[\text{Ni}(\text{H}_2\text{O})_6]^{2+}$, $[\text{Cr}(\text{H}_2\text{O})_6]^{3+}$, etc. The d–d absorption spectra of these complexes allow the parameter k to be derived for each metal ion. With these parameters to hand, one can then determine the values of h for Cl^- , NH_3 , ... from the spectra of chloro, ammine, and other complexes. The set of h and k values shows good consistency on going from one complexed metal ion to another. For what would be the *optical basicity* model, the strategy adopted is to restrict the donor atom to oxygen (always in the oxidation state of -2 and denoted oxide(-II)), and therefore to regard the coordination by the aqua ligand as a particular case for oxide(-II) ligands. In short, this scheme has the great interest in allowing the complexation of metal cations by silicate, borate, etc. to be considered in terms of molecular orbital theory, that is, in terms of the nephelauxetic effect.

In practical terms, however, obtaining B_{complex} from d–d absorption spectra is complicated. Fortunately, past

investigations have shown that one can avoid much difficulty by using instead the s–p spectra of $(n-1)d^{10}ns^2$ metal ions such as Pb^{2+} and Tl^+ [4]. Their UV absorption bands, which arise from transitions to the $(n-1)d^{10}ns^1np^1$ configuration, are Laporte allowed and very intense, even for the nominally spin-forbidden $^1S_0 \rightarrow ^3P_1$ band. This band has the lowest energy and usually presents itself with a clearly defined frequency maximum, which we label ν . Significantly, this frequency has features in common with B_{complex} so that it can be used for estimating covalency changes in the oxide(-II) bonding with the metal ion. For example, the frequency ν is linearly proportional to the h parameters of Cl^- , Br^- , NH_3 , etc. However, since the frequency shifts for the variation of B_{complex} on the one hand and the $^1S_0 \rightarrow ^3P_1$ ($6s \rightarrow 6p$) on the other arise from very different mechanisms, the extrapolated frequency values of ν_f for the Pb^{2+} and Tl^+ ions in the free gaseous state (that is when h is zero) will not necessarily be exactly the experimental values. Indeed, this was found to be the case, with ν_f equal to $60\,700\text{ cm}^{-1}$ for Pb^{2+} and $55\,300\text{ cm}^{-1}$ for Tl^+ (experimental values for the free ions being, respectively, $64\,391$ and $52\,393\text{ cm}^{-1}$). These optical-spectroscopy results and others [4] were regarded as promising for constructing an acid–base scale suitable for measuring the basicity of melts and glasses.

Already there is a defined zero, which is the free ion value of the $^1S_0 \rightarrow ^3P_1$ frequency, ν_f , for $(n-1)d^{10}ns^2$ ions – admittedly an “adjusted” free ion value. Initially, attention was directed mainly toward the Pb^{2+} ion on which to construct the basicity scale (although the Tl^+ and other ions were also used). In order to avoid the many problems associated with the idea of “100 % covalency,” pragmatically crystalline calcium oxide was chosen for unit optical basicity. The Pb^{2+} ion in the highly basic CaO environment has its $^1S_0 \rightarrow ^3P_1$ band frequency, ν_{CaO} , at $29\,700\text{ cm}^{-1}$, and hence the frequency range from 100 % ionicity to the CaO environment, $(\nu_f - \nu_{\text{CaO}})$, is $60\,700 - 29\,700\text{ cm}^{-1}$, i.e. $31\,000\text{ cm}^{-1}$. Writing ν_{medium} for the probe-ion frequency in the medium under investigation, for example, a glass, one defines the optical basicity, Λ , by analogy with the Racah B parameter as the proportional energy change, $(\nu_f - \nu_{\text{medium}})/(\nu_f - \nu_{\text{CaO}})$ [2]:

$$\Lambda = \frac{(60\,700 - \nu_{\text{medium}})}{31\,000}, \quad (4)$$

or, for when Tl^+ is used,

$$\Lambda = \frac{(55\,300 - \nu_{\text{medium}})}{18\,300}. \quad (5)$$

When the probe ion is added to the melt (e.g. as a 10^{-3} molar nitrate), the salt readily decomposes, and the metal ions occupy the sites presented by the network medium (we can usually ignore the small quantity of oxide(-II) that

is generated). An example of the use of Eq. (4) is for Pb^{2+} dissolved in a sodium borate (20 mol % Na_2O) glass (Figure 1), where ν_{medium} is $45\,000\text{ cm}^{-1}$ and therefore $\Lambda = 0.51$. Usually although not always, optical basicity is quoted to two decimal places, but for comparative purposes it can be useful to have three places. Of course, it is necessary that the glass has good UV transparency, although fluorescence spectroscopy can also be used for lower-quality samples.

With the accumulation of optical basicity data for a variety of glasses, the next step is to consider how Λ is related to chemical constitution. In addressing this question, we return to the artificial model, which is the starting point of optical basicity, and consider how the array of oxide(-II) ions becomes neutralized by the constituent cations. For example, in the glass CaO-SiO_2 (40 : 60, mol ratio), taking the formula as $\text{Ca}_2\text{Si}_3\text{O}_8$, it is seen that neutralization would be one quarter by the Ca^{2+} and three quarters by the Si^{4+} . In the general case, these are the *equivalent fractions* of the oxides $X(\text{oxide A})$, $X(\text{oxide B})$, etc. Additionally, however, the tendency for covalency causes the electron donor power of the oxide(-II) ions (atoms) to be further decreased, being affected more by the silicon than by the calcium. With this simple picture, a new factor is introduced, the *basicity moderating parameter*, symbol: $\gamma_A, \gamma_B, \dots$, such that

$$\Lambda = \frac{X(\text{oxide A})}{\gamma_A} + \frac{X(\text{oxide B})}{\gamma_B} + \dots \quad (6)$$

This equation is the fundamental expression of optical basicity.

For a binary oxide, $X(\text{oxide})$ is unity and Λ is simply $1/\gamma_M$, so Eq. (6) becomes

$$\Lambda = X(\text{oxide A})\Lambda(\text{oxide A}) + X(\text{oxide B})\Lambda(\text{oxide B}) + \dots \quad (7)$$

Following this, use is often made of relationships of the type

$$\gamma_A = \frac{X(\text{oxide A})}{\{\Lambda - X(\text{oxide B})/\gamma_B\}} \quad (8)$$

It is important to use Eq. (7) with caution because an isolated binary oxide might behave with a different γ value when present in glass. This happens for P_4O_{10} in the $\text{Na}_2\text{O-P}_2\text{O}_5$ glass system when, initially, its Λ value, 0.48, appears to decrease with addition of Na_2O , so the 1 : 1 glass unexpectedly has the same optical basicity as that of the original phosphorus(V) oxide. Lithium borate glasses behave similarly when the stereochemistry of boron changes from trigonal planar to tetrahedral. For silicate systems, however, this complication seldom arises, so it has been consistently found that γ is 2.100 ± 0.001 for silicon. By Eq. (8), it thus becomes possible to obtain the γ_M values for other metal ions using the spectroscopically obtained Λ values that are available (Table 1). These are substituted into Eq. (6) to calculate Λ of the medium,

Figure 1 Optical absorption spectrum (in the UV region) of Pb^{2+} probe ion dissolved in sodium borate glass (20 mol % Na_2O). Pathlength: 1.5 mm; Pb^{2+} concentration (nominal): $1.1 \times 10^{-3}\text{ M}$. Note: Increasing wavenumber corresponds to decreasing wavelength, e.g. $30\,000\text{ cm}^{-1} \equiv 333\text{ nm}$ and $50\,000\text{ cm}^{-1} \equiv 200\text{ nm}$.

Table 1 Original (pre-2002) values of γ_M for cations^a and Λ for binary oxides.

Cation	Basicity moderating parameter, γ_M	Optical basicity, $\Lambda(\text{oxide})$
Lithium	1.00	1.00
Sodium	0.87	1.15
Potassium	0.73	1.4
Cesium	0.60	1.7
Calcium	1.00	1.00
Strontium	0.9	1.1
Barium	0.87	1.15
Magnesium	1.28	0.78
Aluminum	1.65	0.60
Silicon	2.10	0.48
Boron	2.35	0.42
Phosphorus	2.5	0.40

^a See Table 3 for post-2002 values.

thereby allowing one to correlate the chemical formula of the glass or slag with its physical and chemical properties [4]. Thus it is possible to predict changes in physical/chemical properties from changes in the chemical formula of the melt.

Sometimes it is necessary to consider two important questions: (i) whether the probe ion occupies already existing sites or whether it “misbehaves” and generates its own site and (ii) whether or not the optical basicity changes when the melt transforms to a glass, and vice versa. These two questions are intermingled and have been given careful consideration. As described below, it has gradually become apparent how Pb^{2+} , Tl^+ , and various other probes play a valuable role for investigating glass, especially the chemical bonding and structure.

3 Redox Equilibria in Network Melts

Molten silicates, borates, and others are excellent solvents for redox equilibria many of which have technological application (Chapter 5.6). In extraction metallurgy, for example, it is vital to understand how chemical composition affects the ability of the slag to remove troublesome impurities from the molten metal ([5] and Chapter 7.4). In the case of sulfur that is present in molten iron, this property is measured as the sulfide capacity, C_S , (defined as $(\%S) \times \sqrt{(P_{\text{O}_2}/P_{\text{S}_2})}$, where $\%S$ is the weight % of sulfur in the slag and P_{O_2} and P_{S_2} are the equilibrium partial pressures of O_2 and S_2). Experimental data for silicate and aluminosilicate blast-furnace slags at 1500°C show that the overall reaction expressed by Eq. (2) is related to the slag optical basicity by

$$\log C_S = 12.0\Lambda - 11.9. \quad (9)$$

As a more basic oxide is added, the increase in melt basicity results in the production of further nonbridging oxide(-II). For example, expressing this process as

one represents the transfer of the oxide(-II), initially in an electrovalent environment of CaO , to the silicate melt where it reacts with bridging $\text{Si}-\text{O}-\text{Si}$, thereby producing charged $\text{Si}-\text{O}^-$ units. The bonding between the Ca^{2+} ions and the anionic framework is essentially ionic since a charge of around +1.2 has been estimated to “reside” on the calcium. The balancing negative charge is spread over the oxide(-II) atoms, being more concentrated for the nonbridging oxide(-II)s than for the bridging. The optical basicity idea does not envisage unit negative charge on the nonbridging oxide(-II)s nor a zero charge for bridging oxide(-II)s. The overall charge

increases with increasing optical basicity, which can be thought of in terms of the tendency for the anionic network to provide oxide(-II) “ions” for participation in Eq. (2). Many slag studies have been undertaken by extraction metallurgists for dealing with a wide range of impurities, such as sulfur, phosphorus, water, and so on [5].

Turning now to glassmaking, we note that the presence of redox ion pairs such as the $\text{Fe}^{3+}/\text{Fe}^{2+}$ couple often requires careful control of melt composition to stabilize the desired oxidation state [6]. Because of experimental difficulties, investigations have been limited to just a few ion pairs. It has been found that in contrast to the observation made above for sulfur, increasing optical basicity favors the upper oxidation state. To account for this feature, the metal ions are considered initially as being in the isolated, free state, a condition for which Λ is by definition zero. Both ions are unstable to the extent of their ionization energies, that is, the sum of the first + second for Fe^{2+} and the first + second and third for Fe^{3+} . Increasing Λ of the melt corresponds to an increasingly negative environment, and this effects stabilization for both metal ions through chemical bonding in the formation of the $[\text{FeO}_6]$ or some other chromophore. Because of the larger cationic charge for the trivalent ion, however, a greater optical basicity is required for Fe^{3+} . This extra charge can be pictured as being fed through electron delocalization (mainly by π -bonding) from the nonbridging oxide(-II)s generated in Eq. (10). The stabilization of upper oxidation state ions by increasing optical basicity is probably general (except for $\text{Cu}^{2+}/\text{Cu}^+$) and is satisfactorily expressed in terms of two empirical parameters, a and b :

$$\log \left\{ \frac{[\text{lower state}]}{[\text{upper state}]} \right\} = a - b\Lambda. \quad (11)$$

Results for silicate melts at 1400°C and in an air atmosphere are summarized in Table 2.

Table 2 Relationship of redox ratio, R , for ion couples with optical basicity; $R = [\text{lower state}]/[\text{upper state}]$ in silicate melts at 1400°C in air atmosphere.

Ion couple	Equilibrium	$\log R$
$\text{Fe}^{3+} \rightarrow \text{Fe}^{2+}$	$4\text{Fe}^{3+} + 2\text{O}^{2-} = 4\text{Fe}^{2+} + \text{O}_2$	3.2–6.5 Λ
$\text{Cr}^{6+} \rightarrow \text{Cr}^{3+}$	$4\text{Cr}^{6+} + 6\text{O}^{2-} = 4\text{Cr}^{3+} + 3\text{O}_2$	8.2–13.7 Λ
$\text{Ce}^{4+} \rightarrow \text{Ce}^{3+}$	$4\text{Ce}^{4+} + 2\text{O}^{2-} = 4\text{Ce}^{3+} + \text{O}_2$	5.5–8.3 Λ
$\text{Sn}^{4+} \rightarrow \text{Sn}^{2+}$	$2\text{Sn}^{4+} + 2\text{O}^{2-} = 2\text{Sn}^{2+} + \text{O}_2$	0.6–3.6 Λ
$\text{As}^{5+} \rightarrow \text{As}^{3+}$	$2\text{As}^{5+} + 2\text{O}^{2-} = 2\text{As}^{3+} + \text{O}_2$	5.2–8.9 Λ

The optical basicity model is not restricted to glasses and melts but applies equally well to aqueous solutions [7]. Electrode potential data in acidic and basic aqueous solution at 25 °C have provided a means for predicting a and b for several ion pairs for which no directly obtained results (at 1400 °C) are available. By similar means, Λ has been correlated with the tendency for precipitation of the element out of the molten glass, for example, platinum, silver, and lead.

It is of interest that early attempts to create a scale for basicity involved many studies of glasses containing redox ion pairs and correlating their equilibria with glass composition. UV/visible spectrophotometry was often used. With color changes occurring for decreasing basicity, commonly chosen ion pairs and their chromophores were $\text{Cr}^{6+}/\text{Cr}^{3+}$ (yellow owing to $[\text{CrO}_4^{2-}]$)/(green, owing to $3d^3$ $[\text{CrO}_6]$); $\text{Mn}^{3+}/\text{Mn}^{2+}$ (red owing to $3d^4$ $[\text{MnO}_6]$)/very pale pink (owing to spin-forbidden d^5 $[\text{MnO}_6]$); $\text{Ce}^{4+}/\text{Ce}^{3+}$ (orange owing to charge transfer)/colorless (owing to $[\text{Ce}^{3+} 4f^1 \rightarrow 5d$ band in the UV]); and the stereochemical change of Co^{2+} deep blue [tetrahedral CoO_4]/pale pink [octahedral CoO_6].

4 Optical Basicity and Electronic Polarizability

To explore the possibility of a more “fundamental” optical basicity scale, investigation can be made into the relationship between Λ and the oxide(-II) electronic polarizability. The real part, n , of refractive index of glass is a measure of the reduction in the velocity of the photons as they induce oscillating distortions of the electron charge clouds when they pass through (Chapter 6.1). The electronic polarizability, α , expresses the ease of exercising this distortion for the particular cations and anions of the glass. These values are more or less fixed, except for oxide(-II) where $\alpha_{\text{oxide(-II)}}$ varies over a wide range. In a glass the value of $\alpha_{\text{oxide(-II)}}$ is part of the total electronic polarizability, α_{mol} : one obtains it, therefore, by subtracting the total cationic polarizabilities, $\sum \alpha_i$, and dividing by the number of oxide(-II) atoms assumed in the formula of the glass:

$$\alpha_{\text{oxide(-II)}} = \frac{[\alpha_{\text{mol}} - \sum \alpha_i]}{\text{total oxide(-II)}}. \quad (12)$$

Use of the Lorentz–Lorenz relationship

$$\alpha_{\text{mol}} = \left[\frac{3V_m}{4\pi N} \right] \times \left[\frac{(n^2 - 1)}{(n^2 + 2)} \right], \quad (13)$$

allows α_{mol} (in $\text{\AA}^3$) for the glass to be calculated (assuming isotropy) from the refractive index, n (usually the sodium D line), and density, ρ . In Eq. (13) V_m is the molar volume

(formula weight/density) and N is Avogadro’s number. As an example, we take the glass of mole percentage composition 0.33 Na_2O ·0.095 CaO ·57.2 SiO_2 , which has a refractive index of 1.529 and density of 2.652 g/cm^3 . Its arbitrary formula weight in grams is $(33.3 \times 61.98 + 9.5 \times 56.08 + 57.2 \times 60.08)$, and V_m is $6033/2.652 = 2275 \text{ cm}^3$. From Eq. (13), α_{mol} , the polarizability of the glass, is 278.25 $\text{\AA}^3$. We subtract the cationic polarizability of Na^+ , Ca^{2+} , and Si^{4+} , i.e. $\sum \alpha_i = 17.33 \text{ \AA}^3$ (using values of α_M in Table 3), and divide by the number of oxide(-II) atoms assumed in the formula of the glass, i.e. 157.2. The $\alpha_{\text{oxide(-II)}}$ polarizability is therefore $(278.25 - 17.33)/157.2$, i.e. 1.660 $\text{\AA}^3$.

To derive now the sought-after “fundamental” optical basicity scale, the substitution into Eq. (6) is made using the most reliable basicity moderating parameters, namely, of calcium(II) and silicon(IV). Their γ_M values are 1.00 (by definition) and 2.00 (cf. Section 2), respectively. In 2002, published refractivity data (n and ρ) were available for 15 calcium silicate glasses from 39.0 to 57.5 mol % CaO . From these data, values of α_{oxide} are obtained as indicated above, and Eq. (6) gives Λ_{glass} values for each of the glasses. When plotted together with the same data for crystalline SiO_2 and CaO (Figure 2), these data reveal the relationship very close to [8]:

$$\Lambda_{\text{glass}} = \frac{[(3.133\alpha_{\text{oxide(-II)}} - 2.868)^{1/2}]}{1.567} - 0.362. \quad (14)$$

Significantly, unlike the probe-ion method for measuring Λ , this new one is noninvasive and avoids the possible probe-ion misbehavior noted in Section 2.

For many glasses the optical basicity ranges from approximately 0.3 to 0.65, an interval for which Eq. (14) can be simplified to:

$$\Lambda_{\text{glass}} = 0.699\alpha_{\text{oxide(-II)}} - 0.547. \quad (15)$$

In principle, Eqs. (13) and (12) then (14) or (15) allow the optical basicity of a (binary) silicate glass to be calculated from its density and refractive index and the γ_M value to be obtained from Eq. (8). The values derived in this way are listed in Table 3. Mostly they differ only slightly from the earlier probe-ion method; lithium seems the single exception.

5 Chemical Reactions: Changes in Structure and Bonding

For technological reasons, the interaction of SiO_2 with CaO , Na_2O , etc. usually takes place in the lower-melting cullet. The optical basicity of SiO_2 is 0.48, corresponding

Table 3 Electronegativity, x_M , polarizability, α_M , and $\alpha_{\text{oxide(-II)}}$ in binary oxides; basicity moderating parameter, γ_M , also in glasses.

Oxide	x_M	$x_O - x_M$	x_O	% ionicity	α_M ($\text{\AA}^3$)	$\alpha_{\text{oxide(-II)}}$ ($\text{\AA}^3$)	γ_M
Cs ₂ O	0.79	1.49	2.28	80	2.42		0.66
Rb ₂ O	0.82	1.51	2.33	73	1.40		0.70

P ₂ O ₅	2.19	1.45	3.64	17	0.00	1.33	2.1 ^c

^a For fourfold coordination; for sixfold, $\gamma_{\text{Mg}} = 1.65$, $\gamma_{\text{Al}} = 2.48$, $\gamma_{\text{Si}} = 3.15$.
^b For threefold coordination; for fourfold, in borate glasses, $\gamma_{\text{B}} = 4.2$.
^c Varies in phosphate glasses.

Figure 2 Plot of oxide(-II) polarizability, $\alpha_{\text{oxide(-II)}}$, versus optical basicity of calcium silicate glasses, 39–57.5 mol % CaO (Λ range, 0.60–0.69). Data for SiO₂ and CaO at the extremes ($\Lambda = 0.476$ and 1.000, respectively). Ignoring the data point for CaO, the line fits Eq. (14).

to a Λ -difference between SiO₂ and these bases usually of well over 0.5. Similar differences are evident for borate, phosphate, and the glasses of certain other oxides. For many of these glass systems (though not for silicates),

however, the increase in the experimental Λ varies irregularly with glass composition. This occurs for borate glasses where γ_{B} , which is 2.47 for both vitreous and crystalline B₂O₃, deviates markedly from Eqs. (6) and (7) upon addition of alkali to the glass. This is observed in the UV spectra of Pb²⁺ and Tl⁺ probe ions and also with the far-infrared frequencies of “rattling” Na⁺ ions [9]. The most obvious cause of this effect is the well-known structural change of boron from trigonal planar to tetrahedral coordination ([1], Chapter 7.6). One of the most important results of this change is the elimination of the π -component from the bonding of oxide(-II)s that are attached to the four-coordinated boron atoms. The π -bonding in glass is normally important for the delocalization of electronic charge and for the benefit that this undoubtedly has for reactions occurring in the glass or melt. Thus, the newly formed tetrahedral BO₄[−] units become “stops” embedded in the overall electron delocalization associated with the glass structure.

An interesting feature of chemical bonding in inorganic compounds is that the σ -component serves to transfer negative charge from the donor to the acceptor atom. Normally this is supplemented by some degree of π -bonding, which allows further donation of negative charge. In addition, π -bonding can provide “back-coordination” where some of the negative charge spills back to

the donor atom. This scheme of bonding is recognized as a means for preventing the buildup of positive or negative charge in a molecule and is known as the (Pauling) *electroneutrality principle*. In the case of the BO_4^- units, we have been discussing that the absence of π -bonding means that any back-coordination cannot occur; there is the possibility that in the BO_4^- unit the negative charge resides mainly on the boron atom. Accordingly the basicity moderating parameter, γ_B , of the boron atom is appreciably higher than for trigonal planar boron. This idea of an increase in γ_B is supported by an analysis of the refractivity data for alkali borate glass systems where calculated values of $\alpha_{\text{oxide(-II)}}$ are substituted into Eq. (14). The results show how Λ for each glass increases only very slowly for initial additions of alkali oxide, whereas for lithium oxide there is a *decrease* in Λ up to a Li_2O content of approximately 25 mol %. It appears that the γ_B value for tetrahedral boron is counter-effective to the increasing basicity of the relatively feeble alkali oxide. When Eq. (8) is adapted to accommodate also the (unknown) γ_B value for tetrahedral boron, calculations reveal that the γ_B value for tetrahedral boron is 4.7 [10] on the slightly false assumption that exactly two are generated by each added oxide(-II) atom.

At this point, there is an important question. Does the *chemical behavior* of a series of glasses, such as the stabilization of upper/lower oxidation states of metal ions (Section 3), follow the same trend as the calculated optical basicity, for example, in the case of borate glasses when the calculation assumes γ_B equal to 2.47 for threefold coordinated boron and 4.7 for fourfold. Experimental data for the redox ion pairs $\text{Cr}^{6+}/\text{Cr}^{3+}$ and $\text{Ce}^{4+}/\text{Ce}^{3+}$ indicate that such a parallel does indeed exist. For these ion pairs there is the usual trend of the upper oxidation state being favored by increasing alkali oxide content, but this trend is very slight for initial additions of oxide to boric oxide, and, dramatically, for Li_2O , the trend is the *reverse* for both ion pairs. It is only after approximately 25 mol % Li_2O that the more usual effect of upper oxidation state stabilization occurs. This startling trend almost exactly parallels the trend in the calculated optical basicity, making the result highly significant. It illustrates how *deviations in predicted optical basicity* are paralleled by corresponding *deviations in chemical behavior*. Looked at in another way, deviations in the properties of a glass system with composition, often described as “anomalous behavior,” can be understood, at least partially, in terms of a chemical bonding analysis of the type described here. It also emphasizes the importance of π -bonding in the glass network and the consequences if it is lost.

Another aspect concerning the combination of optical basicity and chemical bonding is the success for identifying the ionic/covalent nature of the sites

provided by a glass as metal ions travel through. Studies of phosphate glasses and melts and especially of borate glasses indicate that sites of higher rather than of lower optical basicity are favored by mobile metal ions (and vice versa) [9]. For example, subjecting a 35 mol% Na_2O sodium borate glass, coated with a thallium–Hg amalgam and floating on mercury, to an electric field results in driving Tl^+ ions into the glass [6]. After sub-surface cleaning with an ion beam, the UV spectrum of the Tl^+ ions indicates the existence of sites of optical basicity equal to 0.66–0.67, which is much greater than expected for this glass. The assistance to ionic mobility might be anticipated for sites where the interaction with oxide(-II) is more covalent, as signaled by the large Λ , since the influence of large lattice energies is bound to be less important. Similar experiments using lead rather than thallium show little movement of Pb^{2+} ions into the glass. Instead, O^{2-} ions migrate to the lead electrode, with formation of PbO , while Na^+ ions are converted to sodium at the mercury electrode. This leaves a volume of the original sodium borate glass that is devoid of Na_2O : it has become a volume of vitreous boric oxide. The mechanism proposed for this reversible reaction involves a “handing over” of oxide(-II) ions between threefold and fourfold coordinated boron atoms [11].

For the interaction of silicates with phosphates, borates, etc., or even with other silicates, there is sometimes the problem of deciding which “salt” is the acid and which is the base. For example, when considering the equilibrium

does twice the amount of alkali oxide in Na_2SiO_3 on the left-hand side compensate for the stronger basicity of K_2O in $\text{K}_2\text{Si}_2\text{O}_5$? Calculations with Eq. (6) show that Λ is 0.65 for $\text{K}_2\text{Si}_2\text{O}_5$ and 0.69 for Na_2SiO_3 , indicating that Na_2SiO_3 is the base. Furthermore, on the right-hand side, Λ is 0.76 for K_2SiO_3 and 0.61 for $\text{Na}_2\text{Si}_2\text{O}_5$, so the *optical basicity differences* are 0.04 and 0.15 for the left- and right-hand sides, respectively. It follows that Eq. (16) represents an acid–base neutralization and should proceed from right to left, which indeed is found to be the case. This consideration of Eq. (16) illustrates how, within a material, chemical bonding results in an uneven distribution of electrical charge and how optical basicity reflects the extent of the negative charge borne by the anionic moiety, presumably on its surface. Thus, when two materials of different Λ are in contact, there exists a chemical driving force that, ideally, is proportional to the optical basicity difference [12]. There are of course many factors influencing reactions of this type, for example, high lattice energy. Nevertheless, examination of sub-solidus compatibility diagrams (as summarized in the

American Ceramic Society's *Phase diagrams for ceramists*) does indicate many instances supporting the idea that optical basicity is an important factor.

The involvement of Λ in the acid–base neutralization for solids discussed above suggests that there might be a similar situation for aqueous conditions through the existence of a relationship with Brønsted acidity. This idea has been tested with suitable sets of pK values for appropriate parent acids, for example, phosphoric acids. In addition to orthophosphoric acid, H_3PO_4 , phosphorus(V) forms several condensed oxyacids containing both bridging and non-bridging oxide(-II)s. Equation (6) gives Λ for each conjugate base (γ_M is set arbitrarily at unity), and one can plot these values against the pK (conjugate acid) values of the various phosphate (and other) species. A roughly linear relationship is obtained, which, moreover, includes the points for water, namely, the bases H_2O and OH^- [4].

6 High and Low Optical–Basicity Materials

It is seen from the periodic table that the nearest neighbor to oxide(-II), with its outer $2s^2 2p^6$ configuration, are fluoride(-I) with the same configuration and sulfide(-II) with the configuration $3s^2 3p^6$. To what extent does the optical basicity model extend to the chemistry of these adjacent elements?

In view of the extra unit nuclear charge, fluoride systems (with no other anion) might be imagined to have optical basicities that are one half of the corresponding oxide systems. It is possible that this situation is equivalent to “one electron worth” of screening in the case of oxide(-II). Probe-ion studies made with Pb^{2+} for molten alkali fluorides remarkably support this idea. Further support comes from polarizability results for crystalline binary fluorides and also complex compounds such as alkali fluoroborates, fluorosilicates, and fluoroaluminates. These results mean that it is possible to use Eq. (6) for calculating the optical basicity of a fluoride glass, but with the condition that the γ_M values are double those for the corresponding oxides, alternatively, by using Eq. (7), but with the oxide Λ halved. It is apparent that with $\Lambda(\text{fluoride}) = \frac{1}{2}\Lambda(\text{oxide})$, some fluoride materials have very low optical basicities, for example, Λ is 0.23 for crystalline $\text{Na}[\text{BF}_4]$ and is 0.35 for the glass $0.100 \text{ MgF}_2 \cdot 0.283 \text{ CaF}_2 \cdot 0.231 \text{ SrF}_2 \cdot 0.386 \text{ AlF}_3$. Mixed fluoride–oxide melts and glasses have been prepared and their refractivity Λ values discussed comparatively with all-oxide glasses [13, 14]. In these media the Pb^{2+} probe ion shows that it is responding to a single, mixed oxide–fluoride environment rather than to two distinct environments.

Sulfide(-II) systems are at the other extreme of optical basicity. From the point of view of chemical bonding, some are semiconductors and are close to electron itineracy, for example, mercury(II) sulfide with a band gap $E_g = 2.10 \text{ eV}$. Studies of optical basicity for semiconductors present difficulties, but in recent years various investigations have been undertaken on sulfur, selenium, and tellurium semiconductor-type materials (e.g. [15]). For crystalline ZnS , a more amenable semiconductor, Pb^{2+} , has its $^1\text{S}_0 \rightarrow ^3\text{P}_1$ frequency at $20\,400 \text{ cm}^{-1}$ in zinc blende and at $19\,700 \text{ cm}^{-1}$ in wurtzite. These yield $\Lambda = 1.30$ and 1.32 respectively, that is, a significantly greater basicity compared with $\Lambda = 0.91$ for ZnO . Trends for MgS , CaS , SrS , and BaS in electronegativity and polarizability fit into the same pattern as for fluorides and oxides.

Perhaps it is surprising that the optical basicity of water itself has been subjected to so little study. It will be recalled that in the development of the nephelauxetic effect (Section 2), Jørgensen set h for H_2O as unity. One of the reasons for this assignment was the consistency of d–d spectral data for $[\text{M}(\text{H}_2\text{O})_n]^{z+}$ chromophores (n , normally six), and with $h = 1.00$ and $\Lambda = 0.39$ for H_2O . However, it appears that when the constricted conditions of the coordination sphere are removed, Λ for the free H_2O molecule rises to 0.51. Further work in this area is called for.

It is of interest that “less related” anionic systems have been investigated, for example, molten chlorides, where probe ions indicate the possibility of establishing a chloride optical basicity scale [2]. Acid–base titrations, for example, have been performed with molten AlCl_3 .

7 Optical Basicity and Electronegativity

It is not surprising that there should be a link between electronegativity, x , and optical basicity since both schemes are concerned with unequal sharing of electronic charge in chemical bonding. In terms of the basicity moderating parameter, γ_M , and the Pauling-type electronegativity, x_M , it has long been established [1] that

$$\gamma_M = \frac{(4x_M - 1)}{3}. \quad (17)$$

with the condition that this relationship is restricted mainly to the M cations having the outer s^2p^6 configuration, thereby excluding most transition metal ions. This condition also applies for Eq. (18).

Although for binary oxides x_O is usually assigned a value of around 3.5, closer inspection shows that this value refers only to the “covalent” oxides (see Table 3). However, with increasing ionicity in the metal–oxide

(-II) bonding, there is a marked decrease in x_O . The effect is shown in Figure 3 where the points (unlabeled for clarity) are for the oxides shown in Table 3. Most lie close to the relationship [12]

$$x_O = \frac{4.1 - 0.86}{(x_M - 0.25)}. \quad (18)$$

The reason for this decrease in x_O is that the increasingly negative charge on the covalently bound oxide (-II) atom renders it reluctant to acquire further negative charge. It becomes unstable with a tendency to lose an electron and to form the peroxide, $(O-O)^{2-}$, or superoxide, $(O-O)^-$, ion. Generally, the electronegativities that are assigned to the elements, in a particular oxidation state, are taken as “fixed,” but the oxide(-II) species stands out as a gross exception. Indeed, the trend shown by Figure 3 is an *abnormality* compared with the other elements in the periodic table. It might be argued that it is this feature that allows optical basicity to operate in a significant way.

The non-fixed character of x_O has a profound effect on the use of electronegativity as an indicator for trends in ionicity or covalency. In general, it is the electronegativity difference that denotes such a trend, as in the series from iodide to bromide to chloride. However, this scheme has limited application for oxides. As seen in Table 3, the electronegativity difference between Na_2O and SiO_2 hardly exists, $x_O - x_{Na} = 1.65$ and $x_O - x_{Si} = 1.67$, even though Na_2O is ionic, whereas SiO_2 is covalent; similar cases are ionic BaO and amphoteric Al_2O_3 where for both, $x_O - x_M$ is 1.86. Among others, these considerations show that for binary oxides of general formula M_aO_b , it is

the decreasing value of x_O that signals increasing ionicity in the metal–oxide(-II) bonding. The value of $x_O - x_M$ for each binary oxide in Table 3 is obtained from its enthalpy of formation, Q (in electron volts, that is, $-\Delta H_f^\circ/96.48$, with ΔH_f° in kJ/mol) divided by the “number of bonds,” b (two for CaO , four for SiO_2 , etc.), where Q requires the addition of 1.13 eV per oxygen because of the double bond in the O_2 molecule. On the Pauling scale, the electronegativity difference, $x_O - x_M$, is given as

$$x_O - x_M = \left[\frac{(Q + 1.13b)}{2b} \right]^{1/2}. \quad (19)$$

Assuming x_M to be invariant, then one obtains x_O by addition (Table 3). The relationship of for example (17–19) leads to the following expression linking the heat of formation of a binary oxide, M_aO_b , with its optical basicity [16]:

$$\frac{Q}{b} = 2 \left[\frac{2.85 - 1.16\Lambda(M_aO_b) - 0.75}{\Lambda(M_aO_b)} \right]^2. \quad (20)$$

This relationship has been applied to silicates and aluminosilicates. For example, $CaO \cdot Al_2O_3 \cdot 2 SiO_2$ requires use of Eq. (20) for each of the three constituent oxides, followed by addition of the relevant Q values to obtain the total Q for the compound. Results have shown that with some refinements to Na_2O and K_2O (see Figure 3), there is a convincing correlation of Q with the optical basicity of the compound. Since Λ is related to chemical constitution through Eq. (6), it is apparent that optical basicity offers a method for calculating the heat of formation of a silicate or an aluminosilicates from its chemical constitution [16].

It is surprising that in the past, with some exceptions, the chemical bonding aspects of glass have tended to be ignored or considered only at a fairly elementary level. Usually the approach is in terms of valence-bond theory with the depiction of electron pairs. Alternatively it is in terms of band theory where electrons are “accommodated” in energy bands. How does the concept of optical basicity connect with these approaches? As explained in Section 2, it is already apparent that optical basicity itself is derived from a molecular orbital approach in exploiting orbital expansion parameters. This connection has allowed calculations for binary oxides (using ionization energies for isoelectronic sets of free ions) that provide estimates of charge-cloud sharing and hence of the ionicity of M^{Z+} (see Table 3). Although they incorporate arbitrary assumptions (as do other atomic/ionic parameters, e.g. ionic radii), nevertheless, these data are useful for comparative purposes. In effect, optical basicity serves to indicate ranking in the ionic/covalent character of the chemical bonding in a similar way that electronegativity difference does for simple non-oxide(-II) compounds.

Figure 3 Plot of oxide(-II) electronegativity, x_O , in binary oxides M_aO_b , against electronegativity, x_M (see Table 3). Points at bottom left-hand area are for “ionic” oxides; those at the top are for “covalent” oxides.

For a glass or melt, it is the uneven spread of electron density over the electronic surface of the “molecules” (for want of a better word) that is responsible for many of its properties, for example, as a reaction medium for redox equilibria.

Historically, a related point of interest concerns the Lorentz–Lorenz relationship, Eq. (13), and how the molecular polarizability, α_{mol} , replaced the molar refractivity R_m (in cm^3) in the Clausius–Mossotti expression:

$$R_m = \frac{V_m(\kappa - 1)}{(\kappa + 2)}, \quad (21)$$

where V_m remained the molar volume, in cm^3 , but, κ , the dielectric constant, became n^2 (Maxwell, strictly at infinite wavelength). When Eq. (21) is written as

$$\frac{R_m}{V_m} = \frac{1 - 3}{(\kappa + 2)}, \quad (22)$$

it is seen that as the value of V_m decreases and approaches R_m (effected by compression or chemical substitution of a metal oxide “bronze,” for example), κ approaches infinity. This condition corresponds to a *polarization catastrophe* and the onset of metallic bonding. In terms of simple band theory, the energy gap (or band gap), E_g , becomes zero as the valence band and conduction band merge into each other. Indeed, the plot of E_g for oxides reveals a close proximity to the empirical expression [17]:

$$E_g = 20 \left(\frac{1 - R_m}{V_m} \right)^2, \quad (23)$$

which implies again that E_g is zero when $V_m = R_m$.

It should be noted that the quantities of both R_m and $\alpha_{\text{oxide(-II)}}$, together with Eq. (23), have, all three, optical basicity as their common link. There are many occasions when chemical bonding is regarded in terms of a sliding scale from covalent to ionic (for example, see Table 3). However, this description is often inadequate, especially when so many materials are viewed in terms of dielectrics, semiconductors, and metals (or insulators, semiconductors, and conductors). Such inadequacies confront glass science. As far as oxide glasses are concerned, Figure 4 is relevant in providing a small selection of binary oxides in an attempt to illustrate these aspects of bonding. The horizontal scale denotes covalent to ionic (through Pauling-type electronegativity, x_O), and in addition, progressing upward from that scale, there is increasing tendency for electron itineracy. The latter feature might be described as the “metallic component” of bonding, increasing with decreasing E_g and with the upper limit (the metallic regime) at E_g equal to zero. To indicate

Figure 4 Schematic bonding chart for binary oxides (abbreviated for clarity): covalency to the left-hand side and ionicity to the right; height indicates closeness to nonmetal-to-metal transition.

the unifying approach provided by optical basicity for these types of chemical bonding, the alternative to E_g , namely, $(1 - R_m/V_m)$, is taken as the vertical scale (see above). The diagram implies that increasing electron itineracy can be a feature regardless of the ionic/covalent nature of the bonding of the oxide. A more complete diagram is discussed by Edwards et al. who also considered the onset of metallicity generally [17].

8 Perspectives

The Lewis idea of chemical bonding, where a base is a donor of electronic charge and an acid an acceptor, is well suited for many inorganic oxide(-II) materials and has been implicit in the present review. Under chemical conditions, the electronic state of oxide(-II) has a flexibility that is greater than for any other element. This accounts for its wide range of electronegativity, x_O , of its electronic polarizability, $\alpha_{\text{oxide(-II)}}$, and of its ability to donate charge when acting as a Lewis base. All of these features are incorporated into the optical basicity model.

At the heart of optical basicity is the existence of a hypothetical array of oxide(-II), O^{2-} , ions. These are influenced by the constituent cations, Ca^{2+} , Si^{4+} , ..., according to the extent that they balance the overall negative charge, that is, according to their equivalent fractions, X_{Ca} , X_{Si} , In addition, there is unequal sharing

of the charge density in the chemical bonding. The combination of the two effects determines the electronic state of the oxide(-II) in terms of its power to react as a Lewis base (for example, in breaking up the silicate network; see Eq. 10) and in terms of its electron donor power (for example, in its coordination with probe cations). The overall effect is expressed, for the cation, as its basicity moderating parameter, $\gamma_{\text{Ca}}, \gamma_{\text{Si}} \dots$, and for the compound as the optical basicity, Λ , according to Eq. (6).

This model is set in the context of well-established chemical theory and incorporates a background of molecular orbital theory and orbital expansion phenomena. The effective functioning of optical basicity and its universal application, which also includes catalysis and geochemistry, are because of this “pedigree.” Inorganic oxidic materials, from network glasses and melts on the one hand to aqueous solutions on the other, are amenable to the optical basicity approach [6, 7, 18].

Practically, optical basicity started with probe ions (Pb^{2+} , Tl^+) and the quantitative treatment of the orbital expansion effect in their electronic spectra, mainly in the UV/visible (optical) region of the spectrum. The optical basicity scale derived from these data correlates well with the chemistry and physics of the media. This provides a means for predicting the trends in properties for a series of glasses using Λ values calculated from chemical constitution with Eq. (6). Noninvasive methods for measuring optical basicity, such as the use of oxide(-II)-1s energies [19], oxide(-II) polarizabilities ($\alpha_{\text{oxide(-II)}}$; see Section 4), or cation rattling frequencies in the far-infrared region [9], have extended the usefulness of optical basicity. They help to provide much needed insights into the nature of chemical bonding in glass and for the interaction with hosted cations, whether static or field driven.

Generally, the optical basicity model implies two important facts about the structure and bonding of glass that, at the present, are often overlooked. First is the existence of electron delocalization (analogous with aromaticity in organic chemistry, though perhaps to a lesser degree), and second is the absence of whole electron charges, for example, on nonbridging oxygen atoms. By implication, the overall existence of some degree of π -bonding must be assumed. For borate systems, partial loss of this feature, accompanying the switch from threefold to fourfold coordination, accounts for some anomalous behavior. Deeper study into these features, not only for borate but for phosphate, germanate, and other glasses, will lead to a better understanding of the mechanism for field-driven ion transport, including movement of O^{2-} ions through the glass [6, 11]. Acquiring a better understanding of chemical bonding, especially the onset of metallization, is vital for the development of glass science, so glass continues to expand its role as a future material [17].

*Nothing tends to the advancement of knowledge as
the application of a new instrument*

Sir Humphry Davy (1778–1829)

1 Introduction

As indicated by the Latin term *acidus* (from *aceo*, to be sour, deriving from *acer*, sharp, piercing), the notion of acidity has very long been familiar even though it was understood poorly. As a reminiscence of the atomic theory of Democritus (ca 470–380), the chemist Nicolas Lémery (1645–1715) [1] still assigned acidity to tiny particles when he wrote that “the acidity of a liquor consists in sharp salt particles, which keep moving.” As evidences, he explained, were the tingling on the tongue caused by acids or the fact that “not only all acid salts crystallize as spikes but all dissolutions of different matters caused by acid liquors are taking the same figure upon crystallization.” Differences in acidity then simply resulted from differences in the size and sharpness of these particles.

The concept of *base* is much more recent. Because of the close association traditionally made between acids and salts, it was heuristically propounded by another famed chemist, Guillaume-François Rouelle (1703–1770), to describe “the substance that serves as a basis” (*base*, in French) to an acid for the precipitation of a salt [2]. In spite of the tremendous progress that followed Lavoisier’s chemical revolution at the end of the eighteenth century, however, a precise definition of relative acidity–basicity along with ways to measure it remained lacking. It was

in 1909 that work made in Copenhagen at the Carlsberg Laboratory on the effect of acidity on proteins led S.P.L. Sørensen (1868–1939) to define pH, for *pondus hydrogenii* (hydrogen weight), as the cologarithm of the hydrogen ion concentration in an aqueous solution [3]. Thanks to progress made in the thermodynamics of solutions, Sørensen redefined in 1924 his fundamental concept of pH in terms of the *activity* of the hydrogen ion [4]. From the equilibrium dissociation of water into H⁺ and OH[−] ions, it then followed that a solution is acidic or basic depending on whether its pH is lower or higher than 7, respectively.

The usefulness of these definitions would have been very limited, however, had not means to measure hydrogen activity been devised. It is in this respect that glass had a considerable impact by having made measurements possible as soon as the pH concept was defined. The *glass electrode*, whose centenary was commemorated in 2009 [5], was in effect a fundamental invention. Its working principle is rather simple: it is the electromotive force (emf) produced when cations are exchanged between the glass surface and the investigated solution. But the phenomena actually involved are much more complicated than long thought, so a theoretical understanding of the glass electrode has long been lagging behind its various applications. Actually, the possibility to vary at will the composition of glass electrodes was a critical factor in their successful design. These could thus be customized to work over specific pH and temperature ranges and, in addition, used to measure the activity of other singly charged cations such as the alkalis, Ag⁺, or even NH₄⁺, illustrating how a successful concept can then be applied to unsuspected fields.

To describe these features, the various kinds of glass electrodes and their uses will be first presented. We will then show how the determining influence of chemical composition on the properties of the glass

electrode may be in turn used to investigate the structural role of cations in glass. As made in particular by the School of Nikolskii–Schultz at Leningrad/St. Petersburg (SPb) University, the successive steps to understand theoretically the glass electrode will be reviewed finally.

2 Types and Properties of Glass Electrodes

2.1 The Glass Electrode

At the origin of the glass electrode were the bioelectric experiments made by the physiologist Max Cremer (1865–1935). Knowing that glass possesses electroconductivity, he investigated the emf of a cell made up of a glass membrane connecting two aqueous solutions and found that it varies with the difference in their acidity/basicity [6]. But it was the electrochemist F. Haber (1868–1934), of ammonia synthesis fame, and his PhD student Z. Klemensiewicz who shortly afterward took advantage of the phenomenon to design the *glass electrode* as an instrument for determining acid–base titration curves that had the great advantage over the Pt|H₂ electrode in that it was insensitive to redox potential and devoid of the possible catalytic action of Pt on the solution [7].

Both Cremer and Haber worked with an industrial glass whose electrical resistivity was quite high. To reduce the resistance of electrode, glass membranes were thus made very thin, even after Mac-Innes and Dole had optimized their sensitivity with a 22% Na₂O · 6% CaO · 72% SiO₂ glass [8]. Such fragile and not very sensitive glass electrodes remained used only for laboratory research until they found in the late 1930s the innumerable applications still known today as a result of further glass optimization to make the bulb sturdier, of electronic amplification of the weak emf signal, and of the design of portable instruments fully incorporating the electronics along with both glass and reference electrodes as made by the then UCLA faculty George Beckman (1900–2004) with his instrument, which he named *pH meter*.

A glass electrode is made of two different glasses, one for the insulating tube and the other for a thin membrane that is most often blown as a bulb (Figure 1a). To restrict the pH measurement to the bulb area, the former has a resistivity from five to seven orders of magnitude higher than that of the bulb, with typical values of 10¹⁶ and 10¹⁰ Ω m, respectively [9]. Thanks to the limitless shapability of glass, the membranes may be easily formed to the requirements of particular applications, e.g. flat sensors for surface measurements (on skin or paper) or in small volumes of solutions or as a spear for measurements in soil, meat, etc. To perform the

Figure 1 Three kinds of glass electrode design for pH and pM measurements. (a) “Classic.” (b) Combined. (c) With a reversible alloy-based solid internal contact.

measurements a glass electrode requires an external reference electrode. A typical modern pH probe thus is a combination electrode where the HCl solution filling the tube ensures the electrical contact with the glass membrane and encloses an Ag/AgCl reference electrode (Figure 1b).

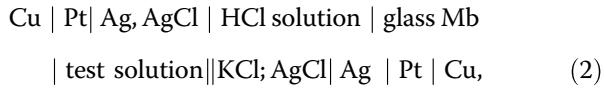

2.2 pH Measurements

In aqueous solutions all ions have a water solvation shell, so the H⁺ ion is just a convenient fiction with which a variety of more complex species, such as the hydroxonium ions (H₃O⁺), are accounted for thanks to the fact that the chemical potential of H⁺ is by definition identical in all such species for systems in internal thermodynamic equilibrium (e.g. [10]). In pH determinations, the H⁺ concentration is expressed in moles of solute per volume of solution (mol/dm³). Following IUPAC recommendations (2000–2002), we will then define pH as

$$\text{pH} = -\text{p}a_{\text{H}} = -\log \left(\frac{m_{\text{H}}\gamma_{\text{H}}}{m^{\circ}} \right), \quad (1)$$

where m is the concentration expressed in molalities (mol/kg), γ_{H} is the activity coefficient of H⁺ ions and $m^{\circ} = 1 \text{ mol/kg}$.

For measurements with a glass electrode, a commonly used galvanic cell is

where $\parallel$ indicates a diffusive barrier. The symmetry of the cell aims at canceling out any potential created at interfaces and, thus, at ensuring that the measured emf only results from the contrast between the test and HCl reference solutions. Operationally, an important parameter is the pH interval where the Nernst equation is valid, namely,

$$E = E^0 + \frac{2.3RT}{F \log a_{\text{H}}} = E^0 - \frac{2.3RT}{F \text{pH}}, \quad (3)$$

where E is the emf of the cell (2) minus the potential of the reference electrode (usually immersed in a 3.5 mol/dm³ KCl solution), E^0 is the standard potential at $a_{\text{H}} = 1$ (or pH = 0), R is the gas constant, T is the absolute temperature, and F is Faraday's number. The value of E^0 includes the diffusion potential at the boundary of the two solutions (which may be eliminated by appropriate means) and the potential at the inner side of the glass membrane, which is not constant but depends on temperature, on the inner solution composition, and on changes in the glass surface induced by the solution.

In view of this complexity, a glass electrode cell is calibrated by means of standard pH buffer solutions before measurements are made. Graphically its pH response in a Nernstian E -pH plot is a straight line whose slope can be considered constant over a definite pH range (Figure 2). The width of this Nernstian range depends on temperature, composition of the electrode glass, and nature and concentration of the acid and singly charged

cations in solution. At high pH, the observed positive deviations from linearity (i.e. the so-called *alkaline errors*) are caused by interferences between H^+ and alkali cations. At low pH, *acid errors* represent deviations from linearity toward negative E values that are due not only to the electrode response itself but also to interferences caused by high anion concentrations.

The membranes of modern pH glass electrodes are produced from lithium silicate glasses to which other oxides are added. As a result of complex optimization, their compositions typically fall in the ranges (in mol %) 21–33 $\text{Li}_2\text{O} \cdot 1\text{--}4 \text{ Cs}_2\text{O} \cdot 3\text{--}5 \text{ La}_2\text{O}_3$ [or Nd_2O_3 , Er_2O_3] $\cdot 1\text{--}4 \text{ CaO}$ [or BaO], where the complement to 100% is SiO_2 . Lithium silicates constitute the base glass because of their high chemical durability and relatively wide region of pH response. Addition of alkaline earth oxides CaO (or BaO) somewhat extends this region toward high pH values, whereas rare earth oxides do so toward low pHs and in addition increase the chemical durability of electrodes with respect to acidic and alkaline solutions. The average values of these oxide concentrations characterize the so-called *universal* glass electrode. These electrodes may be used for general applications at temperatures near ambient showing the Nernstian linear response in a 0–13 pH range in electrolyte solutions with M^+ concentration of 0.1 mol/dm³. Glasses with lower Li_2O concentrations can work at higher pH and higher concentration of interfering alkali ions in solution. Although they are working well at higher temperatures, their high resistance prevents them from being used near ambient. On the contrary, lower working temperatures can be achieved with higher Li_2O concentrations, but the range of linear response then becomes shorter.

2.3 pM Measurements

As made for the H^+ ion, it was early observed that glass electrodes of appropriate compositions are also reacting to concentration changes of other singly charged cations. In analogy with pH, pM scales for the activities of these cations have thus been defined as

$$\text{pM} = -\log a_{\text{M}}. \quad (4)$$

As made of sodium or lithium silicate glasses containing considerable concentration of Al_2O_3 and some B_2O_3 [5], these electrodes show a reversible response to various cations, mainly Na^+ but also K^+ , NH_4^+ , Li^+ , Ag^+ . In the subacid, neutral, and alkaline solutions containing only one of the specified cations, they show almost Nernstian M^+ response for concentrations ranging from saturation to about 10^{-4} mol/dm³. In the presence of other cations, this interval is shorter. They are less common used than pH glass electrode but are nonetheless rather widespread.

Figure 2 Extent of linearity of the E -pH relationship of a 22 mol % Na_2O silicate glass electrode in solutions: 1 – $c_{\text{Na}} = 0.1$ mol/dm³; 2 – $c_{\text{Na}} = 3$ mol/dm³.

2.4 High-Temperature Glass Electrodes

Glass electrodes with a solid internal contact have been developed to extend the temperature range of measurements up to 200 °C. The difficulty to be overcome was that when Pt, Au, Ag, Cr, Al, or even Hg is used for connections with the glass membrane, the transition from the ionic conductivity of the glass membrane to the electronic conductivity of the contact metal is not reversible. This results in troublesome potentials that may originate from impurities in the contacting metals and fast potential drift. The principles to be fulfilled for overcoming the problem were formulated by Nikolskii [11]: (i) the electrode process occurring at the boundary between an ionic conducting membrane and an electronically conducting contact must of course be itself reversible; (ii) the exchange current of the process must be sufficiently large compared with the current flowing through the system under measurement; (iii) any side process must be prevented at the boundary.

These requirements are satisfied with the metal solid contact invented at Leningrad/St. Petersburg University [5, 12], which consists of a thin layer of an alkali metal alloy evenly spread over the inner surface of a glass membrane. Alloys such as LiIn, LiSn, NaSn, or KPb are formed with the same alkali as present in the glass and the electrode is sealed under vacuum to prevent the alkali from reacting with water vapor. These alloys are electronic conductors in which metal ions are diffusing. Exchange of alkali M^+ ions on the alloy/glass interface takes place according to the reaction

which establishes electrochemical equilibrium and governs the electrical potential at this interface. Because of mutual saturation of the phases, the electrode potential does not depend on the volume of the phases and, thus, to within large limit, on the gross composition of the alloy. In this way potentials are highly reproducible, and E^0 values can be so stable as permitting in some instances to use factory calibrations. An additional advantage is a wide working temperature range, which, for instance, allows these glass electrodes to be sterilized at 150 °C with water steam.

2.5 Glass Electrodes for Redox Measurements

For performing redox measurements other important glass electrodes were elaborated by Pisarevskii et al. in the 1960s [5, 12] on a different basis since the electronic conductivity and activity of electrons relies here on the variable valence states of $Fe^{3+,2+}$ and $Ti^{4+,3+}$. With the compositions (mol %) 10 $Li_2O \cdot 5 Na_2O \cdot 18 Fe_2O_3 \cdot 67 SiO_2$ (type I glass, synthesis under reducing conditions) and 10 $Na_2O \cdot 5 K_2O \cdot 29 TiO_2 \cdot 5 Ti_2O_3 \cdot 3 Nb_2O_5 \cdot 50.5 SiO_2$ (type II glass, synthesis

under an argon atmosphere), their electronic conductivity is four orders of magnitude higher than those of their ionic components. To ensure a reversible contact with the glass membrane, a chemical coating of silver or copper is deposited on the inner surface of the glass electrode in contact with the metal wire.

These glass electrodes can be simply prepared with a glassblower torch. Their chemical inertness and sufficient exchange currents cause them to behave like noble metal electrodes in reversible redox systems such as $Fe^{3+,2+}$, $Fe[CN]_6^{4+,3+}$, quinone/hydroquinone, etc. In addition, they are insensitive to the gaseous components of redox systems such as $(1/2) Cl_2(g)/Cl^-$, $H^+/(1/2)H_2(g)$, or $O_2(g)/H_2O$. Not only are these electrodes well suited to measure redox potentials in various systems under aerobic conditions, but they can also be selected for systems where other electrodes commonly used for redox measurements faces difficulties. In the study of the system Ce^{4+}/Ce^{3+} (redox potential $E_H = 1.44$ V), the use of Pt electrodes, for instance, suffers from two side processes, namely, oxidation of the electrode material along with decomposition of cerium solutions on the Pt surface with evolution of oxygen from water, whereas a glass electrode is free of such limitations.

These glasses are actually semiconductors because their conductivity is electronic in nature. When used to prepare electrodes, they result in a special sensitivity to the level of the redox potential of the solution. By *selectivity* we mean here that the electrode can partially equilibrate with a system i regardless of the presence of a competing system j [13]. The effect is due to special features of the energy distribution among the charge carriers in the surface layers such that n -type semiconductors are selective to redox systems with a low E_H , e.g. -0.38 V for the Eu^{3+}/Eu^{2+} system, whereas p -type semiconductors are selective to high E_H systems, e.g. 1.44 V for the Ce^{4+}/Ce^{3+} system. In both cases the E_H values are outside the thermodynamic stability limits of water [14]. Glass electrodes are thus valuable for these applications because they are indifferent in a wide range of redox potentials and pH solutions, thanks to their high chemical stability, as illustrated by kinetic parameter study of the reaction $Ti^{3+} + O_2$ (for the system Ti^{4+}/Ti^{3+} , $E_H = -0.11$ V) in the presence of molecular oxygen in the solution [15].

3 Glass Structure as Viewed by the Glass Electrode

3.1 The Electrode Method

From the middle of the 1950s, the Nikolskii–Schultz School carried out systematic research on electrode properties of glasses of $M_2O-R_xO_y-SiO_2$ systems [16], where

Figure 3 Structural role of elements as determined from electrode properties of alkali silicate glasses. Solid lines: experimental E -pH curves; dashed lines: calculated values with Nikolskii's Eq. (9). Glasses: M_2O - SiO_2 . M_2O is the first modifier, SiO_2 is the first network former (1); M_2O - R_xO_y - SiO_2 . R_xO_y role: 1', 1'' is the second modifier; 2, 3, 5 are the second network formers; and 4 is the intermediary. The straight line aa' is the hypothetical H^+ function $c_{M^+}^{sol} = \text{const}$.

$M = Na$ or Li was the initial network modifier, Si the initial network former, and R any other element incorporated. The electrode method to study glass structure is based on the fact that, when part of SiO_2 is replaced by R_xO_y , differences in the pH response (E -pH curves) with respect to that of a binary M_2O - SiO_2 glass depend on whether the element R is another network former or another network modifier or is playing an intermediate role.

Ions in glass mutually polarize each other. Here binary alkali silicate glasses M_2O - SiO_2 (15–33 mol % M_2O ; $M = Li, Na$) will be used as references for subsequent comparison. One can consider that their electrode potential is determined only by H^+ ions up to pH 8–10, whereas M^+ metal ions begin to influence the potential at higher pH values (Figure 3, curve 1). The reason is that a binary glass has weak acidic ionogenic groups $[SiO_{3/2}]OH$. The bond strength of hydrogen in these groups is mainly covalent and very strong.

3.2 Effect of a Second Network Modifier

If a network modifier is added as a third oxide R_xO_y to the glass, the ion R^{z+} placed in the environment of an $[SiO_{3/2}]OM$ group polarizes the $O-M$ ($O-H$) bond. This effect is either weaker or stronger than that of the initial M^+

cation. The former case for instance applies to Cs , Ca , or Ba : the $O-H$ bond then becomes stronger, and the linear H^+ response of the glass electrode extends into the higher pH region (Figure 3, curve 1'). For Mg or Be , the opposite holds true: the $O-H$ bond weakens, and the H^+ response linear region narrows down (Figure 3, curve 1''). These phenomena are named the *electrode effect of the second modifier* [16].

3.3 Effect of a Second Network Former

Addition of network-forming ions R^{z+} has dramatic effects as their incorporations into the silicate network induce changes in the coordination number k or in the interatomic distances $R-O$ inherent to the R_xO_y oxide. These cations R^{z+} have so strong polarizing effects that they form their own element silicate ionogenic groups $[SiO_{4/2}] - [RO_{k/2}]^{(k-z)-} (k-z) M^+$ (for simplicity, reference to $[SiO_{4/2}]$ in such groups will be omitted hereinafter). This case is in particular that of Al , B , Ga , and Fe ($z = 3$, $k = 4$) (Figure 3, curves 2 and 3), Sn and Zr ($z = 4$, $k = 6$) (Figure 3, curve 5).

The subsequent exchange of M^+ for H^+ or $M^{+'}$ from the solution results in the formation of the $[RO_{k/2}]^{(k-z)-} (k-z) H^+$ (or $M^{+'}$) groups, which are strongly acidic in H^+ form. The $O-H$ and $O-M'$ bonds in these groups do not differ significantly either in their character (they are mostly ionic) or in their energy. This feature results in an early disruption of the H^+ response (at $pH = 1-3$). If a fairly small quantity (1–4 mol %) of the network-forming oxide R_xO_y is added, then the appearance of $[RO_{k/2}]^{(k-z)-} (k-z) H^+$ groups manifests itself as a "step" in the E -pH curve at pH values from 1–3 to 5–6, followed by a decrease of E caused by the predominance of silicate groups (Figure 3, curve 3). This response is akin to the titration curve of a mixture of strong and weak acids. At higher concentrations of the network formers, the glass electrode responds to pH changes only in the region of the strong acidic solutions, and it shows response to the M^+ ion at pH higher than 3 or 4. In Figure 3 this behavior corresponds to the horizontal parts of curves 2 and 5 at $c_{M^+}^{sol} = \text{const}$. Introduction of oxides of Y , La , and Ti and of some rare earth elements into the glass composition eliminates the acid error and gradually reduces limits of H^+ response. This is the *intermediator effect* (Figure 3, curve 4).

In such studies of E -pH curves for M_2O - R_xO_y - SiO_2 glasses, it was thus possible to determine successfully the structural role of the network-modifying, intermediary, and network-forming ions for about 30 different elements of the periodic system [16]. This method was thus applied to elucidate the structural role of a variety of oxides much earlier than made with direct, structure-sensitive methods (Section II).

4 Theories of the Glass Electrode

4.1 Nikolskii's Thermodynamic Ion-Exchange Theory

Experimental data accumulated in the 1920s gave a sound basis to the first theory of glass electrodes. As formulated in 1937 by Nikolskii [17], the idea that the primary phenomenon at work in both glass electrodes and other ion-selective electrodes is ion exchange has gained general recognition. The ion-exchange equilibrium

is thus established between the glass membrane and the solution, so L^+ cations (H^+) also appear in the membrane. Identical cations also exchange between the membrane and solution

in reactions that are faster than ion exchange. The potential-determining equilibrium will be thus the reactions $H_{Mb}^+ \rightleftharpoons H_{sol}^+$ (7) and (8) in the regions of H^+ and M^+ response, respectively.

It is within the framework of this thermodynamic ion-exchange theory that Nikolskii derived the following equation for the glass electrode potential:

$$E = E^0 + 2.3 \frac{RT}{F} \log (a_{H^+} + K_{H^+,M^+}^{exch} a_{M^+}), \quad (9)$$

where E is the emf of a galvanic cell (2), the parameters E^0 , R , T , F are as defined in Eq. (3), and a_{H^+} and a_{M^+} are the ion activities in the solution.

The exchange constant then is

$$K_{H^+,M^+}^{exch} = \frac{a_{H^+}^{sol} a_{Na^+}^{Mb}}{a_{Na^+}^{sol} a_{H^+}^{Mb}} = \exp \frac{(\mu_{H^+}^{0,Mb} - \mu_{Na^+}^{0,Mb}) - (\mu_{H^+}^{0,sol} - \mu_{Na^+}^{0,sol})}{RT}, \quad (10)$$

where the difference between the standard chemical potentials of the ions in the glass membrane and in the solution $\mu_{i^+}^{0,Mb}$, $\mu_{i^+}^{0,sol}$ reflects the bond-strength differences in these phases.

This constant characterizes the sorption selectivity of the ions by the membrane from the solution as well as the position of the transition region [17]. It is the "influence factor" of the M^+ ion on the H^+ response of the glass electrode that has actually different meanings in different theories.

4.2 Evolution of the Theory

An equation such as (9) cannot describe the whole experimental E -pH curves, in particular, the extended transition from one response to another as well as the stepwise

pH response. These limitations stimulated further development of the theory through the rejection of two important assumptions made by Nikolskii to derive Eq. (9). The first was the unity activity coefficients of both H^+ and M^+ ions in glass, which meant that the activity coefficients γ_i 's were assumed independent of the degree of substitution of one kind of ion by another. The second was the assumption that the sum of the ions concentration in glass (or in the membrane) is constant:

$$c_{H^+}^{Mb} + c_{M^+}^{Mb} = c_R^{Mb} = c^0,$$

where c_R^{Mb} is the concentration of the fixed anionic sites in the membrane.

Two approaches may be distinguished in the subsequent evolution of the theory. On the one hand, the assumption made by G. Eisenman et al. [18, 19] about the nonideality of a glass membrane, i.e. $a_{i,Mb} = c_{i,Mb}^n$, where the parameter n relates the activity of the ion to its concentration, allowed a smooth transition from H^+ to M^+ response to be described successfully.

With another approach, the same result was obtained by Nikolskii et al. [16] on the basis of the concept of various ionogenic groups in glass and their dissociation constants. Moreover, this theory successfully explained the stepwise pH response illustrated by curve 3 in Figure 3.

The concept of the potential of a glass electrode as a phase boundary potential was replaced by the idea of a membrane potential, i.e. a potential drop accounting for those occurring at phase boundaries as well as for diffusion potentials in surface layers on both sides of the glass membrane. Equilibrium at the boundary, which determines the phase boundary potential, then specifies the boundary conditions for the diffusion potential [20]. Experimental evidence for these two phase boundaries has come from studies of the glass electrode potential dynamics and the actual composition of surface layers of some alkali aluminosilicate glasses after the transfer of the glass electrode from HNO_3 or MNO_3 solutions into an $AgNO_3$ solution, and vice versa [21].

4.3 Nikolskii-Eisenman Equation

In many respects the electrode properties of glasses such as the extension and slope of the electrode response or its selectivity depend on the mobilities of ions and on the mechanism of their transport in glass. The Nikolskii-Eisenman equation [16, 19] describes the glass electrode potential as a membrane one:

$$E = E^0 + 2.3 \frac{RT}{F} \log \left[a_{L^+}^{1/n} + \frac{\bar{u}_{M^+}}{\bar{u}_{L^+}} (K_{L,M}^{exch} a_{M^+})^{1/n} \right]^n. \quad (11)$$

Unlike Eq. (9), this expression takes into consideration the nonideality of the glass membrane (through the factor

n), and it also includes the ratio of the ions mobilities in the membrane changing the significance of the “influence factor.” In Eq. (11), E, E^0, R, T, F, a_{L^+} , and a_{M^+} are defined as above, whereas $\bar{u}_{M^+}, \bar{u}_{L^+}$ are the ion mobilities at the glass surface layers, their ratio being assumed to be constant.

The product $(\bar{u}_{M^+} / \bar{u}_{L^+})^n K^{\text{exch}}$ determined from potentiometric measurements is named the potentiometric selectivity coefficient $K_{L/M}^{\text{pot}}$ (or $K_{L/M}^{\text{sel}}$), whereas $K_{L/M}^{\text{pot}}$ and n are empirical parameters, which are characteristic for a particular glass for any given pair of cations. If L^+ designates H^+ , then $n > 1$ and Eq. (11) may be fit to experimental curve. If L^+ is Na^+ and M^+ is K^+ , then as a rule $n = 1$. This equation describes well the glass electrode behavior in the regions of pure H^+ (at $a_{H^+} \gg K_{H/M}^{\text{pot}} a_{M^+}$) or pure M^+ responses (at $a_{H^+} \ll K_{H/M}^{\text{pot}} a_{M^+}$). It also describes well a smooth transition from H^+ to M^+ responses, hence challenging Nikolskii's equation in [17], which did not consider a factor n and predicted a sharp transition from one response to another.

4.4 Processes in the Surface Layers of Glass and the Glass Electrode Potential

A deeper insight into the operation of the glass electrode was achieved through observations of the concentration profiles of ions in glass layers that were altered by interaction with the solution (Figure 4). Along with studies of chemical and electrochemical processes at the glass–solution boundary, these observations have led to

Figure 4 Typical profiles of ion concentrations in the surface layers of glass. I: Steep gradient of Me^+ characteristic of durable lithium silicate glasses, reflecting a “simple” ion interdiffusion. II, III, IV, and V: S-shaped profiles characteristic of sodium silicate and aluminum sodium silicate glasses, indicating ion interdiffusion accompanied by other processes such as dissolution of the glass network or its hydrolysis. The thicknesses of the surface layers involved can be defined as l, l', l'' .

a better understanding of the dynamics of the glass electrode potential and other properties of the glass surface. It has in particular been established that hydrolysis/condensation reactions of the form

and processes such as microphase separation accompany the interdiffusion process in the surface layers that cause their structural transformations and changes in site numbers R^- , so the glass electrode potential changes with time. For this reason, Doremus [22] proposed an equation for the potential of glass membranes consisting of two parts differing in their composition and/or in structure and, accordingly, by their values $\bar{u}_{M^+}, \bar{u}_{L^+}$ and $K_{L/M}^{\text{exch}}$, i.e. $K_{L/M}^{\text{pot}}$. Changes within the interfacial boundary region may cause E change to with t . A multilayer model of an inhomogeneous altered surface layer with m ($1 \dots k \dots m$) sublayers has been proposed [21] to account for this dependence. Experiments have indeed shown that the dynamics of glass electrode potential correlates with the temporal changes in the ionic composition of the glass surface layers.

4.5 Nernst–Planck–Poisson Model

Another modern potentiometric model [23] regarded as promising uses the Nernst–Planck–Poisson (NPP) system of equations to simulate the nonequilibrium response. Unlike in the phase boundary model, electroneutrality and steady-state/equilibrium assumptions are abandoned so that the space and time domains are accessed. The NPP model describes a system consisting of m layers (phases) within which the concentration changes of r components – ions or uncharged chemical species (as it is done in multilevel model) – and a change of the electrical field in space and time take place. The NP equation describes the transport of ions by diffusion and migration, whereas the P equation governs the electrical interaction of the species. The model predicts well an ion-sensor response and also the selectivity and the variability of the lower detection limit over time.

4.6 Baucke's Dissociation Mechanism

Using high-resolution techniques of ion bombardment for spectrochemical analysis (IBSCA) and nuclear reaction analysis (NRA) to study glass surfaces, Baucke [24] gave a most detailed description of the surface layers for lithium silicate glass. He described the state at the glass–solution interface as a dynamic equilibrium both in terms of thermodynamics and electrochemical kinetics. He pointed out that the electrochemical mechanism of the glass electrode potential formation is a consequence

of a process termed *charge division* at the boundary (the dissociation mechanism).

Uncharged surface groups RH and RM are formed because of glass interaction with the solution. Their dissociation results in the appearance on the glass surface of a minute concentration of negatively charged groups R^- , e.g. SiO^- or $SiOAl^-$, depending on the compositions of the glass and of the solution (and in particular of its ion concentrations). These anionic groups provide a density of negative charges on the surface and, therefore, give rise to a negative potential of the glass membrane with respect to that of the solution. Both the concentration of the charged groups and the glass electrode potential are functions of the solution composition $E = f(\text{pH}, \text{pM})$. The reactions of dissociation (and association) of the glass surface groups are in cumulative equilibrium:

and

From the respective equilibrium constants of these reactions, $K_{D,H}$ and $K_{A,M}$, Baucke defined a “selectivity product,” namely, $(K_{D,H} \bullet K_{A,M})$. This product plays a role similar to that of K^{exch} in Nikolskii’s Eq. (9), i.e. it determines whether or not a glass electrode exhibits a pH or pM response and it characterizes the position of the transition region. According to Ref. [24] this “selectivity product” is constant and its magnitude is equal to 10^{-12} .

A thermodynamic treatment of the acid dissociation equilibrium, Eq. (13), yields the equation

$$E = E_H^0 + \frac{RT}{F} \ln \frac{a_{R^{-(s)}}^{(s)} a_{H_3O^+}^{(s)}}{a_{RH}^{(s)} a_{H_2O}^{(s)}} = E_H^0 + 2.3 \frac{RT}{F} \log \frac{a_{R^{-(s)}}^{(s)}}{a_{RH}^{(s)} a_{H_2O}^{(s)}} - \text{pH}, \quad (15)$$

which thus describes the linear pH dependence of the glass membrane potential as it is usually known. This equation also indicates that the potential of the glass is determined by the minute concentration of the dissociated groups, R^- , which are bound to the glass surface and are thus in contact with the solution. Among the significant features of this approach is the theoretical proof of the fact that the experimental slopes of the E –pH (pM) curves are slightly lower than “ideal” ones (namely, 59.16 mV/pH at 25 °C) by lying in the range 58–59.1. This difference exists because the change in the activity of ions H^+ and M^+ is connected with the activity change in the other members of the equilibrium.

5 Perspectives

Elaboration of new glass compositions along with progress in electronics and instrument manufacturing has produced glass electrodes with more robust membranes that could be operated outside the laboratory in a such different contexts as chemical industry, environmental and pollution control, medicine, oceanography, biology, or life sciences. Hence, only temperature probably is a fundamental parameter now measured more frequently than pH! Development of new special glasses for electrodes with a reversible solid contact will expand further applications in wider temperature ranges with the same excellent reproducibility.

The stability of these glass electrodes at high temperature makes it possible to sterilize them with steam under pressure (150 °C) and, therefore, to apply them in biotechnical pH monitoring. They will, for instance, be commonly used all over the world to monitor pH and pM for evaluation of the health level in animals and humans (for example, in their aggressive intestinal tract). Thanks to their insensitivity to gaseous components, redox glass electrode will in addition be utilized for measuring redox potentials in microbiological systems under aerobic conditions where interferences with the system O_2/H_2O will be avoided. Likewise, these electrodes will be fit for measuring pH in Antarctic waters below 0 °C as well as up to 3000 atm in deep ocean depths down to the Marianas Trench (11 km)!

Baucke studies have actually represented a significant advance in understanding the operational mechanism of glass electrode. From a theoretical standpoint, however, the current framework does not account yet consistently for the dependence of the glass electrode properties on the composition and structure of the glass (especially those properties governed by the ionic mobility), for the extended interval of glass electrode potential in the transition region, or for the dynamics of the potential at transition from one response of glass electrode to another. One can thus surmise that a unified theory of the glass electrode will be created on the basis of Nikolskii–Eisenman theory, Baucke’s approach, and multilayer and Nernst–Planck–Poisson models.

Electrochemistry of Oxide Melts

Christian Rüssel

Otto-Schott-Institut, Jena University, Jena, Germany

1 Introduction

Synthetic as well as natural glasses generally contain more or less high fractions of *polyvalent* elements, which may thus occur in at least two different oxidation states even if only under extremely oxidizing or reducing conditions. In industry, these elements are either impurities in the raw materials or added on purpose to the glass batch, for example, as fining or coloring agents (Chapter 1.2). The main physical property of a glass influenced by the redox state is the color, i.e. the transmissivity of light in certain wavelength ranges. To a high extent, this feature determines product quality and may in particular reflect the temperature distribution within the melting tank. Other important properties of glasses that depend upon polyvalent elements are fluorescence and solarization.

Whether for fundamental or industrial reasons, polyvalent elements and their redox properties must be accurately characterized. If electrochemical methods are particularly valuable in these respects, it is because they are well suited for determining not only the thermodynamics of redox equilibria but also the diffusion coefficients of redox couples or the concentrations of polyvalent species even in glasses contained in melting tanks. A significant advantage of these methods is that they are in principle much faster than those involving redox equilibration experiments. As originally developed to study aqueous or organic solutions, electrochemical methods require good ionic conductors, that is, melts containing alkali oxides at concentrations higher than 10 mol % whose conductivity thus is purely cationic ([1], Chapter 4.2).

To review these methods in this chapter, it will be useful to summarize first the basics of redox thermodynamics, referring the reader to Chapter 5.6 for a more complete account. After a brief summary of experimental methods, the thermodynamic determination of redox standard potentials and equilibrium constants will be described. Diffusion coefficients will then be dealt with, followed by voltammetric chemical analyses. Finally, the principle of impedance spectroscopy will be discussed.

Because ionic conductivity strongly depends on temperature, the temperature range for which a specific method can be applied is restricted. As a general rule, the larger the ionic conductivity, the smaller the minimum temperature at which a certain electrochemical method can be applied. An upper limit for an electrochemical measurement is only imposed by the chemical and mechanical stability of the used materials. Since electrodes are generally made out of platinum, the upper limit should be about 1650 °C. The minimum possible temperature also depends on the method used. For example, simple potentiometric experiments, such as oxygen activity measurements, are possible at lower temperatures than voltammetric measurements where current voltage curves are recorded.

2 Thermodynamics of Redox Equilibria

At high temperatures, polyvalent elements in reduced and oxidized forms build equilibria with the oxygen physically dissolved in the melt (O^{2-}):

Reviewers: R. Conradt, RWTH Aachen University, Aachen, Germany
P.-J. Panteix, Institut Jean Lamour, Université de Lorraine, Nancy
Cedex, France

where n is the number of transferred electrons and A^n and A^{n-z} are the redox species in its oxidized and reduced state, respectively. The constant of this equilibrium depends on both temperature and melt composition:

$$K(T) = \frac{a_{A^{n-z}} \cdot a_{O_2}^{z/4}}{a_{A^n} \cdot a_{O_2}^{z/2}}, \quad (2)$$

where a_i is the activity of species i . Except for silver in certain systems (see Section 5), the equilibrium described by Eq. (1) shifts to the right with increasing temperature. In other words, the reduced state is favored with increasing temperature since production of gaseous oxygen causes the large entropy increase associated with the stable high-temperature state by Le Chatelier's moderation principle.

Because the O^{2-} species do not occur in noticeable quantities in most glass compositions, and its activity is in addition unknown, it is more suitable to describe the redox equilibrium by another equilibrium constant $K'(T)$ defined as

$$K'(T) = K(T) \cdot a_{O_2}^{z/2} = \frac{a_{A^{n-z}} \cdot a_{O_2}^{z/4}}{a_{A^n}}, \quad (3)$$

which also depends upon melt composition.

In most glass melts, the concentration of physically dissolved oxygen is much smaller than those of polyvalent ions, so the equilibrium described by Eq. (1) does not shift noticeably upon quenching if no other redox pair is present in the melt [2]. This is the reason why one can determine redox equilibrium constants by equilibrating a melt with an atmosphere of known oxygen partial pressure, quenching the sample and analyzing the A^n/A^{n-z} ratio by appropriate physical or chemical means. But this procedure is time consuming because the needed diffusion of oxygen into or out of the sample tends to be slow under conditions where speeding up of the equilibration process by convection is not possible because of a high melt viscosity. Although the quantity of melt equilibrated with the atmosphere in these experiments is usually as small as a few grams, one should always ensure that equilibrium with the atmosphere is actually reached. An alternative procedure is to measure the oxygen activity of the melt with a ZrO_2 -based sensor. In the literature, numerous studies on redox equilibria relying on such equilibration methods have been reported (e.g. [3]).

In the last two decades, however, redox equilibria have frequently been studied electrochemically [4, 5]. Although the most common method is square-wave voltammetry, impedance spectroscopy is also used. To perform these measurements, electrodes are inserted into the melt, and measurements are directly carried out, typically in the 1000–1600 °C range. In addition to the

redox equilibrium data, diffusion coefficients are also derived from the recorded voltammograms.

According to Eq. (1), the ratio A^n/A^{n-z} depends on the gas atmosphere, temperature, and, furthermore, melt composition. From the equilibrium constant $K'(T)$, the standard Gibbs free energy, $\Delta G^\circ(T)$, can be obtained. If its temperature dependence is also determined, then the standard enthalpy, ΔH° , and entropy, ΔS° , can also be derived from

$$\Delta G^\circ(T) = \Delta H^\circ - T\Delta S^\circ = -RT \ln K'(T), \quad (4)$$

where R is the gas constant. In addition, the standard potential E_0 of the redox pair and its temperature dependence can be determined because it is related to the standard Gibbs free energy, $\Delta G^\circ(T)$, by

$$\Delta G^\circ(T) = -nFE_0(T), \quad (5)$$

where F is Faraday constant and n is the number of transferred electrons.

Empirically, available experimental data have been used to account for the dependence of redox equilibria on melt composition in terms of formulae that account for the contribution of each component by an incremental system, generally with the assumption of a linear effect for each of them. Actually, however, this approach is highly questionable at least for elements such as alumina or boron whose oxygen coordination numbers and structural role vary with the overall glass composition (Chapters 2.4, 7.6) as also mentioned below.

3 Experimental Aspects

In usual laboratory electrochemical measurements, from 50 to 250 g of glass is melted between 1000 and 1600 °C, depending on composition, in a platinum crucible in a high-temperature furnace (for instance, with $MoSi_2$ heating elements). The highest signal-to-noise ratios are obtained if the power supply of the furnace delivers a d. c. voltage. For oxygen activity measurements, the potential between a zirconia probe and a platinum electrode may, for instance, be measured (Figure 1). Whereas the zirconia electrode must be as large as possible, the wire forming the three-phase boundary melt/Pt/air must be as thin as possible to minimize oxygen transport.

If air is used as a reference gas, the oxygen activity, a_{O_2} , of the melt can be calculated with

$$E = (RT/4F) \ln (a_{O_2}/0.21 \text{ bar}). \quad (6)$$

It follows that measurements of a_{O_2} at varied temperatures also enable ΔH° to be calculated.

For voltammetric measurements (Figure 2), three electrodes are inserted into the melt from the top: a platinum

Figure 1 Experimental set up for measurements of oxygen activities in a glass melt.

Figure 2 Experimental set up for voltammetric measurements in glass melts.

wire (1 mm in diameter) as the working electrode, a platinum plate as a counter electrode (size: 2 cm²), and a ZrO₂-based reference electrode flushed with air. These three electrodes are connected to a potentiostat, which is the main part of the electronic equipment because it ensures that the potential between the working and reference electrodes is always equal to the required value. The potentiostat is further connected to a computer, which also controls the desired time dependence of the potential and records the current. The fundamentals of this method are well documented in literature (e.g. [6]).

In square-wave voltammetry, the most frequently used technique, the potential–time dependence is a staircase ramp upon which a rectangular wave ($\tau = 10\text{--}400$ ms, potential amplitude $\Delta E = 100$ mV) is superimposed. One measures the current after each half-wave and then calculates the difference between two consecutive values to derive the standard potential of the redox pair considered. In simple cases, this potential is given by the maximum observed in the current–potential curve (Figure 3). The situation is more complicated if two redox pairs are

Figure 3 Effects of temperature on peak potentials in voltammograms recorded for a 10 Na₂O·10 MgO·10 Al₂O₃·70 SiO₂ (wt %) melt doped with 0.25 mol % Fe₂O₃ [7].

present with overlapping current–potential curves or in any other nonideal case, for instance, if adsorption at the electrode takes place [8]. As described in detail in the literature [9], it is best to deconvolute the curve in terms of experimentally recorded matrix currents and theoretically calculated current–potential curves [6] of the particular electron transfers. Equilibration with the surrounding atmosphere is in fact not necessary because the working electrode has a starting potential – usually 0 mV vs. the zirconia-air electrode – which yields the same redox ratios as achieved upon equilibration with air.

From the peak current densities, i_p , diffusion coefficients can in addition be obtained with

$$i_p = \text{const} \cdot D^{1/2} \cdot C_o \cdot \Delta E \cdot \tau^{-1/2}, \quad (7)$$

where C_o is the total concentration of the polyvalent ion, D is the mean diffusion coefficient of its oxidized and reduced species, ΔE is the pulse potential, τ is the step time of the square wave, and const is equal to $0.31 \cdot \pi^{-1/2} \cdot F^2 \cdot n^2 / (RT)$.

In summary, a simple potential measurement enables first the oxygen activity of the melt to be determined and then the redox ratio to be calculated if the thermodynamics of the redox pair considered is known.

4 Standard Potentials and Equilibrium Constants

To verify the validity of the determined dependence of a redox ratio on oxygen activity, one dopes the melt investigated with the polyvalent element of interest and equilibrates it under different oxygen fugacities at the same temperatures. The redox ratios are then determined independently, for instance, by spectroscopic methods. In a

plot of $\log ([A^{n'}/[A^{n+z}]]$ against $\log (a_{O_2})$, a_{O_2} = oxygen activity, the results define a straight line with an $n/4$ slope. As a matter of fact, all redox pairs studied in this way conform to Eq. (1), so this relationship is experimentally well proved [5].

As a first example, the square-wave voltammograms recorded at different temperatures from a potential of 0 mV for an iron-doped (Na,Mg) aluminosilicate are shown in Figure 3. All curves display a distinct maximum caused by the reduction of Fe^{3+} to Fe^{2+} :

With decreasing temperatures, the peak potential becomes increasingly negative, varying from about -145 mV at 1600°C to -225 mV at 1200°C , thus indicating a shift of the iron redox equilibrium toward the oxidized Fe^{3+} state. In parallel, the strong decrease observed for the peak currents is caused by decreasing diffusion coefficients. As for the final increases of the current at potentials more negative than -500 or -600 mV (depending on temperature), they are due to partial decomposition of the melt into platinum silicide.

More comprehensive results illustrate the effects of changes of either composition or temperature on iron redox equilibrium. The effects on potentials of the substitution of MgO for SiO_2 at 1600°C (Figure 4) [7] are in fact similar to those of decreasing temperatures (Figure 3): increasing MgO concentrations yield more negative potentials through shifts toward the Fe^{3+} state, whereas diffusion coefficients increase notably. This similarity is borne out by comparisons made between the effects of temperature and MgO concentrations on peak potentials whose variations are approximately linear in both cases (Figure 5). The effect of glass composition on the peak potentials also enables conclusions to be derived on the melt structure at the respective temperature, for example,

Figure 4 Effects of (MgO, SiO_2) substitution on peak potentials in voltammograms recorded at 1600°C for $10 Na_2O \cdot x MgO \cdot 10 Al_2O_3 \cdot (80 - x) SiO_2$ melts doped with 0.25 mol % Fe_2O_3 [7].

on the way in which an increasing Al_2O_3 concentration causes Al to be no longer solely incorporated in tetrahedral coordination.

Copper raises more difficulties than iron because the initial reduction of Cu^{2+} into Cu^+ is followed by reduction of Cu^+ into metallic Cu, which can alloy with the Pt electrode. Because the second of the two peaks of voltammograms (not shown) thus has to be discarded, only the peak potentials of the first reaction are displayed in Figure 6 [10] against temperature for Cu-doped sodium aluminosilicate melts with varying Al/(Al + Si) ratios. In these instances, the measurements become increasingly inaccurate above 1000°C because of signal superimposition with matrix currents at positive potentials caused by the decomposition of the glass matrix and the resulting formation of gaseous oxygen. At all temperatures, the peak potentials increase with increasing Al_2O_3

Figure 5 Voltammetric peak potentials as a function of the MgO concentration in glass melts with the basic compositions $10 Na_2O \cdot x MgO \cdot 10 Al_2O_3 \cdot (80 - x) SiO_2$ doped with 0.25 mol % Fe_2O_3 [7].

Figure 6 Voltammetric peak potentials of the Cu^+/Cu^{2+} peak as a function of the temperature in melts with the basic mol% compositions $26 Na_2O \cdot x Al_2O_3 \cdot (74 - x) SiO_2$ doped with 1 mol % CuO [10]. Solid lines: regression lines.

concentration from 5 to 15 mol % and then drop off so abruptly at higher contents that below 1000 °C the most negative peak potential is that of the sample with 20 mol % Al_2O_3 , because then Al_2O_3 is no longer incorporated solely in tetrahedral coordination. Within experimental errors, the potentials again depend linearly on temperature for all studied compositions. The slopes and intercepts of these lines thus directly yield the standard entropies, ΔS° , and enthalpies, ΔH° , of the redox reaction, whose highest absolute values are thus found for the 20 mol % Al_2O_3 sample.

Not surprisingly, a great many voltammetric measurements have been made on soda-lime-silica melts in view of their considerable industrial importance. A selection of data obtained for a variety of redox couples shows that, with the single exception of $\text{Ag}^\circ/\text{Ag}^+$, all peak potentials increase in absolute values with increasing temperatures with distinct but not so different slopes (Figure 7) [11]. As a result, the order of these redox couples remains basically the same at different temperatures. Of course, the values for a given redox couple reflect the particular manner in which both valences are incorporated in the melt structure. Hence, they depend on melt composition as already shown by Figures 4–6. For polyvalent elements

Figure 7 Effect of temperature on the electrochemical series for a glass with the composition 16 Na_2O ·10 CaO ·74 SiO_2 , doped with various types of polyvalent elements [11].

such as iron, tin, and copper, this effect has been studied in detail, so structural models for their incorporation have been proposed [1, 9]. From the broad variety of glass compositions investigated for the $\text{Fe}^{3+}/\text{Fe}^{2+}$ couple, a model of prediction of the peak potential, for instance, has relied on sodium and aluminum speciation to yield

$$E_p(1300^\circ\text{C}) = a + b[\text{Na}_2\text{O}]_{\text{NBO}} + c[\text{Na}_2\text{O}]_{\text{Al}} + d[\text{MgO}] + e[\text{CaO}] + f[\text{Al}_2\text{O}_3]_t + g[\text{Al}_2\text{O}_3]_o + h[\text{SiO}_2], \quad (9)$$

where $[\text{Na}_2\text{O}]_{\text{NBO}}$ and $[\text{Na}_2\text{O}]_{\text{Al}}$ are the Na_2O concentrations of network-modifying and Al charge-compensating sodium, respectively, and $[\text{Al}_2\text{O}_3]_t$ and $[\text{Al}_2\text{O}_3]_o$ are the Al_2O_3 concentrations of tetrahedral and octahedral aluminum, respectively. The fit parameters are $a = 20$ mV and $b = 8.76$, $c = 3.42$, $d = 7.84$, $e = 11.19$, $f = 2.7$, $g = 7.34$, and $h = 2.72$ mV/mol % [1]. Other empirical formulae have been proposed in narrower composition ranges, from which the redox ratios can also be calculated from the glass composition and the oxygen activity. [7, 9]. The $\text{Ag}^\circ/\text{Ag}^+$ redox potential is a special case because it decreases with increasing temperature in Al-free melts (Figure 7), as already noted, and also below 1100 or 1200 °C in aluminosilicate melts before increasing “normally” at higher temperatures [12]. The Ag^+ ion can be a network-modifying or a charge-compensating cation for tetrahedral Al^{3+} , like alkali and alkaline earth cations with which it competes for bonding with either nonbridging or bridging oxygens. The complex voltammetric results thus point to complex structural interactions as function of both temperature and composition, which remain to be investigated specifically.

5 Diffusion Coefficients

In addition to peak potentials, square-wave voltammetric experiments have yielded a wealth of diffusivities for polyvalent elements. Some of them are represented in an Arrhenius plot for a standard soda-lime-silica glass in the rather wide 750–1300 °C range (Figure 8) [13]. As determined from fits made with Arrhenius equation to the experimental data, they range from 3×10^{-17} to 2×10^{-10} m^2/s :

$$D = D_o \cdot \exp(E_a/RT), \quad (10)$$

where E_a is the activation energy and D_o a pre-exponential factor.

At a temperature of 850 °C, the diffusion coefficients vary from 3×10^{-17} to 10^{-11} m^2/s , i.e. by more than six orders of magnitude. The largest are those of silver, known to be very mobile in a glass network, which, for example, makes this element highly suitable for ion

Figure 8 Arrhenius plot of the diffusion coefficients of various polyvalent elements determined in a glass with the basic composition 16 Na₂O·10 CaO·74 SiO₂ [13].

exchange. These diffusion coefficients are in the same order as those of other network modifiers such as alkalis.

The smallest values are those of Cr⁶⁺, which possesses a high charge and seems to be tightly bonded to the glass network. These diffusion coefficients are in the same range as those of silicon. The coefficients of ions with valences from 2 to 4 lie in between the values of Ag⁺ and Cr⁶⁺. As usual, diffusivities conform to a *compensation law* whereby the activation energies of faster diffusing species are lower and, conversely, those of slowly diffusing species are higher (Figure 8). But the large variations of the data plotted illustrate that Stokes–Einstein law is not generally valid because these diffusion coefficients should otherwise vary with the reciprocal of ionic radii, i.e. under no circumstances by more than one order of magnitude at the same temperature. Obviously, the way in which the respective redox species are incorporated in the melt structure plays an important part, and it is of course not simply determined by the ionic radius and the charge of the ion.

Figure 9 Arrhenius plot for the mean diffusion coefficients of Cu⁺/Cu²⁺ for different sodium silicate melts [14].

The strong effects of composition are illustrated by Arrhenius plots of the mean diffusion coefficients of Cu⁺/Cu²⁺ for different sodium silicate melts (Figure 9) [14]. In all cases, the temperature dependence is actually Arrhenian. Although similar values are found for Na₂O concentrations in the 15–26 mol % range, the diffusion coefficients are the smallest for the 15 mol % Na₂O melt, pass through a maximum at 20 mol % Na₂O, and then markedly decrease at higher contents. The surprising result is that copper diffusion coefficients are smaller than in the melt with the highest Na₂O concentration, i.e. with the lowest viscosity [14]. There are thus two competing regimes, namely, the first where Stokes–Einstein equation obtains and the second where copper becomes more strongly incorporated with increasing Na₂O concentration.

6 Voltammetric Sensors: Quantitative Determinations of Polyvalent Elements

Yet another application of voltammetry deals with the quantification of polyvalent elements, which can be performed directly, even in technical glass-melting furnaces where glasses such as green and amber are produced. These materials contain iron, chromium, and sulfur. Chromium occurs in three different valence states, namely, Cr²⁺, Cr³⁺, and Cr⁶⁺ and thus shows the two peaks of the redox pairs Cr^{2+/3+} and Cr^{3+/6+}. Altogether four voltammetric peaks are expected (two for chromium and one for both iron and sulfur) and are actually observed (Figure 10) [15]. The attributed peak potentials are known from laboratory studies of melts that contain only one of these polyvalent elements. If the attributions of peaks to the redox steps Cr^{6+/3+}, Cr^{2+/3+}, and Fe^{2+/3+} are clear, that of the sulfur peak is not. The shape of

Figure 10 Voltammogram recorded for a green glass melt (curve 1) and a melt without any polyvalent element [15]. Difference curve (1-2) decomposed into contributions of $\text{Cr}^{6+/3+}$ (curve 5), sulfur (curve 6), $\text{Fe}^{3+/2+}$ (curve 7), and $\text{Cr}^{3+/2+}$ (curve 8). Curve 4, sum of the simulated curves 5-8.

the voltammogram is always the same, but the origin of the peak, i.e. the attributed redox pair, is not definitely known, possibly because electrode adsorption plays an important part.

But this limitation does not prevent sulfur from being quantitatively determined in the melt (Figure 10). First, a voltammogram is obtained for the melt under study and another for a melt with the same basic composition, but without any polyvalent elements. After subtracting the latter curve from the former, one decomposes with a least squares method the resulting difference into four bands whose peak potentials and full widths at half maximum yield the sought after contents of chromium, iron, and sulfur [15]. In the same base glass composition and at the same temperature, the peak potentials and half-widths do not depend on the respective concentrations.

7 Impedance Spectroscopy

The last technique to be presented is impedance spectroscopy, a fairly versatile tool to investigate glasses and melts. It is, for instance, extensively used in studies of corrosion processes (Chapter 5.10). Examples are corrosion of molybdenum electrodes in contact with glass melts or of ion conductive glass in contact with molten salts. Impedance spectroscopy is also commonly applied to investigate electrical relaxation phenomena, mostly at temperatures below the glass transition, and also phase separation when changes in ionic conductivity allow the temperatures of the transitions, or even their kinetics, to be determined.

By contrast, only a few studies have been performed with impedance spectroscopy on the thermodynamics and diffusion of polyvalent ions in glass melts (e.g. [16]). Here the same three-electrode equipment as used for voltammetric studies is suitable, and a large variety of methods is in principle possible. The method most frequently applied consists in superimposing on a given d.c. potential and a.c. potential with an amplitude of 5–50 mV and a frequency in the 10^{-2} – 10^6 s^{-1} range. Then one simply studies the effect of the d.c. potential by repeating the experiment at different values.

To obtain impedance spectra, the absolute value of the impedance and the phase angle or the real and the imaginary parts are measured and plotted for illustration. The next step involves setting up first a physical model of the processes at the working electrode and then an equivalent circuit composed of resistors, capacitors, and some other impedance elements. A suitable software is finally used to optimize the values of each impedance elements. If the simulated spectrum agrees with the measured values within the limits of the experimental error, the equivalent circuit is assumed to give an appropriate description of the electrode reactions.

Experiments done with three different d.c. potentials on a $16 \text{ Na}_2\text{O} \cdot 15 \text{ Al}_2\text{O}_3 \cdot 69 \text{ SiO}_2$ sample doped with 0.25 mol % Fe_2O_3 illustrate the procedure (Figures 11–13).

Figure 11 Impedance spectra in a melt with the basic composition $16 \text{ Na}_2\text{O} \cdot 15 \text{ Al}_2\text{O}_3 \cdot 69 \text{ SiO}_2$, doped with 0.5 mol % Fe_2O_3 recorded at 1500°C at different superimposed d.c. potentials of -400 mV (a), -150 mV (b), and 0 mV (c) [16]. Solid lines: simulated curves. Please note that the absolute values of impedance and phase angle are drawn.

Figure 12 Equivalent circuit used to simulate the obtained impedance spectra [16]. L , inductivity; R_E , ohmic resistivity of the melt between the working and reference electrodes; R_Ω , resistivity due to the electron transfer reaction; C_D , double layer capacitance; and W , Warburg parameter.

Figure 13 Dependence of the Warburg parameter on the superimposed d.c. potential at various temperatures for a $16\text{Na}_2\text{O} \cdot 15\text{Al}_2\text{O}_3 \cdot 69\text{SiO}_2$ base melt [16].

In spectra recorded at 1500°C in the 10^{-2} – 10^6 s^{-1} frequency range (Figure 11), the absolute value of the impedance is approximately constant and in addition does not depend on the d.c. potential at frequencies higher than $2 \times 10^3 \text{ s}^{-1}$. At lower frequencies, however, the differences become significant, the impedance increasing with the voltage applied. As for the phase angles, they are all negative up to a frequency of $2 \times 10^4 \text{ s}^{-1}$ above which they become positive (NB in Figure 11, the absolute values of impedance and phase angle are drawn). At the lowest frequency (0.1 s^{-1}), the absolute value of the phase angle is the largest and then decreases continuously until the minimum is reached. The curve obtained for -150 mV is clearly different from those recorded at the other potentials.

In a second step, the impedance spectra are simulated with an equivalent circuit (Figure 12), which is the simplest possible suitable to describe the electrochemical experiment. It is composed of the capacitance of an electrochemical double layer C_D , a resistor R_Ω (which is $>0 \Omega$ if the electrode reaction is kinetically hindered), a so-called Warburg impedance W (accounting for diffusion

processes), a resistor R_E (accounting for the limited ionic conductivity of the melt and increasing with decreasing electric conductivity), and an inductance L predominantly attributed to the wiring. For the melt compositions studied, the resistor R_Ω is negligibly small because the temperature is high enough that the electrode reaction is not kinetically hindered during the measurements.

That this equivalent circuit is appropriate is shown by the good agreement found between the simulated and experimental values (Figure 11). Interestingly, most elements of the equivalent circuit do not depend on the d. c. potential. Only the Warburg parameter W does so. It should possess a minimum at the standard potential of the electrode reaction, as borne out by the minima observed at five different temperatures between 1350 and 1550°C (Figure 13) where all points were extracted from individual simulations of the impedance spectra. Actually the Warburg parameter is the largest at 1550°C , where the diffusion coefficient of iron is highest, and decreases with decreasing temperatures. In all cases, a minimum is observed at potentials between -200 and -150 mV . The respective potential is identical with the respective standard potential.

8 Perspectives

Although the majority of electrochemical studies of glass melts have dealt with alkali or alkaline earth silicates and aluminosilicates, some have been carried out on phosphates or borosilicates. In the latter, voltammetric measurements are similar to those made on silicates because the potential range accessible is approximately the same and limited by the same processes, namely, the formation of gaseous oxygen and platinum silicide at positive and negative potentials, respectively. Studies in borosilicate melts have concentrated on a composition suggested for the vitrification of nuclear waste ($57 \text{ SiO}_2 \cdot 12.2 \text{ B}_2\text{O}_3 \cdot 16.8 \text{ Na}_2\text{O} \cdot 11.1 \text{ Li}_2\text{O} \cdot 2.9 \text{ MgO} \cdot 0.2 \text{ ZrO}_2 \cdot 0.1 \text{ La}_2\text{O}_3$) [17]. Thanks to high alkali concentrations and, thus, to high ionic conductivities, measurements have been readily made as a function of temperature for a variety of polyvalent elements, transition metals included. The electrochemical series of elements is similar to that in a soda-lime-silicate glass melt, although the absolute values are somewhat different (compare [11, 17]).

By contrast, electrochemical measurements are difficult to perform in phosphate melts, probably because of high water concentrations. These lead to an increase in current at potentials more negative than 700°C , which is supposedly due to the formation of PH_3 or P_2H_6 . In a glass melt with the composition $\text{NaPO}_3 \cdot 2 \text{ Sr}(\text{PO}_3)_2$, an electrochemical series of elements has nonetheless been

determined. With respect to silicates, the main difference is that the redox pair $\text{Sb}^{3+}/\text{Sb}^{5+}$ has a standard potential that is more negative than that of the $\text{As}^{3+}/\text{As}^{5+}$ redox pair.

Future studies should also focus on polyvalent rare earth elements such as $\text{Ce}^{3+/4+}$, $\text{Eu}^{2+/3+}$, and $\text{Yb}^{2+/3+}$ relevant to luminescent materials (Chapter 6.3), which up to now have not been studied electrochemically. Here, the luminescence should widely be affected by the redox state.

Knowledge of thermodynamic data of redox equilibria is valuable to understand the redox reactions that are taking place when the temperature is changed. Although these reactions are frozen in below T_g , thermodynamics has indeed a stronger effect on these reactions than kinetics.

1 Introduction

Contact between metals and molten oxides takes place in a large variety of industrial processes. The resulting sticking and adhesion phenomena are either an integral component of the process or a drawback to be avoided. For example, preoxidation of a metal part ensures tight sealing with glass in fields as diverse as jewelry, decorative furniture, or electrical and electronic technologies. On the contrary, in glassmaking or glass forming (e.g. Chapter 1.5), sticking between the glass and the mold, crucible or stirrer must be avoided as it may induce defects on the product and corrosion of the tools.

The purpose of this chapter is thus to give an overview of the physicochemical interactions between glasses or melts and metallic materials. Complexity is actually a general feature of these chemical interactions because of the fundamentally different natures of metals and oxide melts. As metals and metallic alloys exhibit a high electropositivity, i.e. an ability to be oxidized to a cationic state, molten oxides are electrolytic solvents that may dissolve ionic species and in addition may act as oxidizing agents. Redox reactions involving dissolved metal and nonmetal species may thus occur in molten silicates and lead *in fine* to the dissolution of metallic solids if the metal and molten glass are in close contact over a wide interfacial area.

To deal with these interactions, the fundamentals of wettability and sticking will first be considered. Then the chemical interactions between glass and metallic alloys will be detailed as they rule the corroded or

passivated state of the metal. This done, the next three sections will be successively dedicated to the key parameters controlling the chemical reactivity of glass/metal interfaces, the methods and techniques used to study them, and finally typical cases of metallic materials corrosion.

2 Wetting, Sticking, and Adhesion Phenomena

Any study of glass/metal interactions must begin with wetting as it is the first step toward either the unwanted corrosion of the metal or the desired sticking and adhesion between the two phases [1]. Referring to recent contributions [2, 3] for a more detailed treatment and other examples, we will first state that the concept of wetting is based on the contact angle (Figure 1) measured between a glass droplet and the relevant substrate. In a first approximation, this angle is evaluated by the classical Young–Dupré equation, namely,

$$\gamma_{sv} - \gamma_{sl} = \gamma_{lv} \cdot \cos(\theta), \quad (1)$$

where γ_{sv} is the solid surface energy, γ_{sl} the solid–liquid interfacial energy, and γ_{lv} the surface tension of the liquid in contact with the vapor phase.

Complete wetting consists in the total spread of the liquid onto the substrate, i.e. $\theta = 0$, whereas partial wetting is obtained for values of θ comprised between 0 and 90°. When wetting occurs it means, therefore, that γ_{sl} is lower than γ_{sv} , the difference ($\gamma_{sv} - \gamma_{sl}$) being its driving force. Many parameters influence the wetting of a molten glass onto a metallic substrate: (i) temperature; (ii) the chemical composition of the surrounding atmosphere, notably its oxygen fugacity; (iii) the roughness and composition of the solid surface, which can be oxidized or not; and

Figure 1 Scheme of a liquid sessile drop in equilibrium with a solid substrate: γ_{sv} is the solid's surface energy, γ_{sl} the solid-liquid interfacial energy, and γ_{lv} the surface tension of the liquid in contact with the vapor phase.

(iv) the composition of the glass, which determines both the rate of spreading and the potential extent of chemical reactions upon reactive wetting.

The wetting experiments made by the “transferred drop” version of the sessile drop technique proposed by Pech et al. [3] takes into account all these parameters (Figure 2). They are performed in a metallic furnace in an atmosphere of purified helium with an oxygen partial pressure lower than 10^{-9} Pa. The device must be equipped with windows so that the drop morphology can be video recorded at high temperature. The contact angle θ and the drop base radius R are then measured directly from the recorded images. The glass must first be introduced into the furnace on an auxiliary substrate. A dynamic vacuum is established ($P_{\text{total}} = 10^{-5}$ Pa), and the temperature is then increased up to 1200°C . This step allows gas bubbles to be removed and fining of the glass specimen to be achieved, typically in two hours. Then, the temperature is decreased down to the chosen wetting temperature (T_w) [3]. At this stage, the drop is raised until it touches the studied substrate to form

gradually a *pendular bridge* through which the melt is transferred to the substrate by capillary forces. Upon cooling, the last step consists in measuring the temperature at which the glass spontaneously separates from the substrate. This *detachment temperature* (T_d) is typically lower than the glass transition temperature (T_g) by several hundred degrees.

As an example, the wetting of a soda-lime glass – with 13.4 wt % Na_2O , 10.9 CaO, 1.4 MgO and 1.6 Al_2O_3 and $T_g = 560^\circ\text{C}$ – on a standard stainless steel substrate will be considered. The following observations are made [2]:

- The contact angle θ ranges from 60 to 70° between 965°C and 1200°C .
- The spreading rate increases with the test temperature.
- The substrate roughness increases the actual contact area and, therefore, causes a decrease of both the contact angle and spreading rate.
- The detachment temperature lies between 100°C and 150°C .
- The metal surface is not oxidized.

Interestingly, these results are not sensitive to changes in the contents of more (Cr, Si) or less (Ni, Co, Fe, Mo) oxidizable elements in the stainless steel. For a platinum substrate, a typical noble metal, the results are similar except for the detachment temperature T_d , which is just 20°C lower. Partial wetting is observed when metals are investigated in a neutral atmosphere. When electro-positive atoms are linked by metallic bonds, wetting is nonreactive and relatively insensitive to the nature of the metal. Adhesion is thus ensured by physical

Figure 2 Successive temperature-time steps of the “transferred drop” variant of the sessile drop technique. (a) Deposition of the glass onto an auxiliary substrate, (b) glass after fining on the auxiliary substrate, (c) drop raised to the test substrate for transfer by capillary contact and formation of a pendular bridge, and (d) hanging glass drop. interactions. These results are consistent with those of Zackay et al. [4]. In contrast, for a vitreous carbon substrate, the contact angle θ and detachment temperature T_d are 135 and 300 °C, respectively. In such a non-electropositive compound characterized by covalent bonds, nonwetting is partial, and adhesion is rather due to van der Waals interactions and is thus relatively weak.

One can improve wetting and sticking by oxidizing the surface of the metal. The cohesion of the formed oxide is due to ionic (or ionocovalent) bonds. The same kind of bond can exist between the oxide and the glass, as the latter is also an ionocovalent compound. Under such conditions, low contact angles are actually measured with the transferred drop technique as a result of a reactive wetting process. In addition, good adhesion is achieved since no detachment is observed ($T_d < 20$ °C), especially when the mismatch between the thermal expansion coefficients of the metal substrate and of the glass is well accommodated by the interfacial oxide layer.

The oxide layer can be formed either at high temperatures in atmospheres with high oxygen contents or by *in situ* oxidation of the immersed metal surface by the oxidizing species initially present or added to the glass [3]. In such cases, the oxide layer is permanently stable if its constituting elements have reached their solubility limit in the molten glass (see Section 3). Clearly, these concentrations are determined by the overall composition of the considered glass matrix. In many cases, however, oxide dissolution in the glass is quicker than its formation at the metal surface [3] inducing corrosion of the metallic solid [5]. A preoxidation treatment of the substrate is then necessary. These various features have been taken into account for developing optimized glass/metal interfaces with noble metals like Pt or Au and, more frequently, with oxidizable metals such as Cu, Ag, Fe, Cr, Fe–Ni–Co (Kovar), Mo, W, Zr, and Ti and their respective oxides [6]. Of course, these are widely used in many applications like sealants for vacuum tubes, incandescent light bulbs, or tight channeling of fuel and oxygen in solid oxide fuel cells [7]. Other promising applications are self-healing materials such as glass–vanadium–boron composites as their oxidation leads to the formation of a $V_2O_5 \cdot B_2O_3$ glass ($T_{\text{melting}} = 700$ °C), which can wet, fill, and heal cracks during service.

3 Control of High-Temperature Chemical Interactions at the Metal/Molten Glass Interface

The chemical reactions occurring at the glass/metal interface are controlled by the chemistry of the melt and the reactivity of the metal with the melt species. Three parameters must be considered. These are (i) the oxygen pressure (pO_2) at the metal/glass melt interface,

which controls redox reactions; (ii) the glass basicity (aO^{2-}), which controls oxo-complexation; and (iii) the temperature, which controls kinetic effects and reactivity through the Gibbs free energy driving forces. These three parameters are not strictly independent. Most elements present in melts can, for instance, react with free O^{2-} ions to form oxo-complexes in a way that also depends on pO_2 , as indicated by the general equation that describes redox equilibrium between two different oxidation states of the same element [8, Chapter 5.6]):

Besides, the potential E is related to the Gibbs free energy ΔG through the relationship: $\Delta G = -nFE$, where F is the Faraday constant (i.e. 96 500 °C/mol) and E is determined from

$$E = E_0 + \frac{RT}{nF} \ln \left(\frac{MO_x^{(2x-m-n)-}}{MO_y^{(2y-m)-} \cdot O_2^{(n/4)} \cdot O^{2-(x-y-n/2)}} \right), \quad (3)$$

where E_0 is the potential at the appropriate standard state, R the gas constant, T the temperature, and n the number of electrons exchanged in the reaction.

For a fixed melt composition, the stability domain of the redox species is summarized on a redox potential scale [5]. The *electroactivity domain* of the solvent is defined by the upper and lower redox couples, which are generally O_2/O^{2-} and Si^{IV}/Si^0 for silicate melts (Figure 3). But the width of this window does in principle depend on melt composition. For example, a high concentration of lead oxide PbO (such as in crystal glass) narrows it on its cathodic side because of the reduction of PbO into metallic Pb (Figure 3).

The solubility of oxides in melts also strongly depends on the melt potential, as illustrated by the chromium solubility or the residual sulfur content [9, 10] curves determined for soda-lime-silicate melts (Figure 4). The variations of oxide solubilities with the redox state of the melt can also strongly influence (and control) the formation (or not) of solid species at the metal/glass interface.

The formation of a layer at the metal/glass interface is summarized by the flowchart of Figure 5. At the onset of the metal/glass contact, the chemical potentials of the relevant components differ in the two phases, which means that the interfacial zone is not in an equilibrium state. Redox reactions are a way to lower these chemical potential differences: either an element of the alloy is oxidized by another of the melt, which is reduced (Figure 5a), or an element of the melt is reduced at the metal/glass interface, followed by subsequent oxidation of an element of the alloy (Figure 5b), resulting in the formation at the

Figure 3 Scale of formal potential (E_f) at 1050 °C of the main redox couples present in glass or constituting alloys with reference to the yttria-stabilized zirconia (YSZ) electrode.

Figure 4 Chromium solubility (at %) and residual sulfur content (wt %) in a soda-lime-silicate melt versus oxygen partial pressure.

interface of an oxide layer and a metallic compound layer, respectively.

Depending on the species that form and on their reactivity with the elements of the melt, several reaction pathways must be considered:

- If an oxide layer forms, the oxide is stabilized at the interface when its solubility in the melt is low (Figure 5e), which limits the progress of the reaction. Alternatively, this oxide can react with elements of the melt to form another compound (Figure 5d). If the solubility of the oxide is high, it dissolves into the melt, which is then locally enriched with an element initially present in the alloy (Figure 5c).
- If a metallic layer forms, the metal can react with the alloy to yield intermetallic compounds through the solid-state (sometimes liquid-state) reactions determined by the phase diagrams (Figure 5f).

For the (c), (d), and (f) pathways, both composition (i.e. aO^{2-}) and melt potential are locally modified at the interface, and so do the chemical properties of the melt. The rate of these local modifications is directly related to the

temperature of the system. If it is very fast, the solvent properties at the interface can markedly change [11] and modify the initial reaction pathway, especially because the diffusion rate of O_2 in the melt strongly depends on the temperature. In addition, the equilibration of the chemical potentials at the metal/glass interface depends on the initial redox state of the glass and on the thickness of the melt layer between the metal and the surrounding atmosphere. Finally, the composition and physical state (solid, liquid, or gaseous) of the phase formed at the interface depend on temperature, so attention should also be paid to the pertinent phase diagrams.

4 Characterization of the Glass/Metal Interaction

Several experimental techniques and methods have been developed to study the formation of layers at the metal/glass interface either from *post mortem* analyses (i.e. qualitative and quantitative metallographic observations) or from *in situ* measurements (electrochemical studies)

Figure 5 Pathway for the formation of layers at the metal/molten glass interface.

[8]. A combination of both methods obviously provides complementary information on the interaction mechanisms.

4.1 "Raw Immersion" Technique

An easy way to observe directly the influence of parameters such as glass composition, temperature, time of interaction, and surface state of an alloy (raw, preoxidized, roughness, etc.) on the reactivity of the alloy is provided by the "raw immersion" technique. With it, corrosion by a molten glass is carried out at a laboratory scale. A metallic sample is totally or partially immersed at high temperatures in a crucible filled with an appropriate amount of glass, the second configuration involving the presence of a triple point. After a given period of time, the sample is removed from the melt and quenched in air. A heat-shrinkable tube can be applied around the sample in order to preserve the glass surrounding the metal/alloy, which may crack upon quenching. All characterization methods of solids (scanning electron microscopy, electron probe microanalysis, etc.) can then be used to determine the morphology of the layers formed at the metal/glass interface and to investigate various features such as dissolution, reaction with the elements present in the melt, stability of the oxide layer, or reaction of the metallic elements with the metal. In addition,

corrosion rates can be determined from measurements of the thickness variations of the sample.

4.2 Electrochemical Methods

4.2.1 General Principles

As molten glasses exhibit a significant ionic conductivity, they are considered as good electrolytes. The use of electrochemical techniques is thus appropriate to characterize the various redox reactions involved in the corrosion of materials by these media. Because many such techniques may be used, only the most common in corrosion studies will be reviewed. Electrochemical measurements in molten glass are made in the same way as in aqueous media. The potential is controlled between working and reference electrodes, whereas the current density is measured between the working electrode and a counter electrode. Electrochemical measurements in molten glass require the use of specific materials that can withstand the harsh conditions imposed by high temperatures and contact with the molten silicate. Refractory ceramic materials (e.g. alumina, mullite, refractory cements) are recommended for constructing the electrodes, and noble metals such as platinum and Pt–Rh alloys are favored for the wires providing the electrical contacts.

The reference electrode must have a constant electrochemical potential in a given glass. Yttria-stabilized

zirconia (YSZ) is preferably used for this purpose thanks to its stability at high temperatures and to its high conductivity for O^{2-} ions that is at the root of the use of the redox couple O_2/O^{2-} as a reference. The counter electrode must be inert and present a maximum surface area to optimize current collection.

Depending on the nature of the study, two types of working electrodes are used. For characterization of glass properties, the working electrode also has to be chemically inert: noble metals are mostly used. For characterization of the metal/glass interaction, the electrode is made up of the studied metal in the form of a rod [5] or embedded in a ceramic tube letting a cross section serving as a surface electrode (Figure 6).

The nature of the crucible containing the glass is another important issue. A ceramic crucible is a low-cost solution. Its main disadvantages are brittleness, possible pollution by reaction with the glass sample, and the use for only one glass sample. A metallic (nonnoble) crucible is thus a better choice providing it is first subjected to polarization at a potential low enough to allow reduction of silicon, which will then be reoxidized into a protecting silica layer. As to noble metals, they suffer from their cost but have the dual advantage of high chemical stability and possible use as a reference and/or a counter electrode [11]. In this case, the existence of a triple point must be taken into account as it will cause a perturbation of cathode curves if gaseous oxygen is reduced into oxide ions in the melt.

When positioning the electrodes, the solution resistance must be minimized by keeping the tips of the electrodes as close as possible, especially for the reference and the working electrodes. The electrolyte resistance between these electrodes causes an ohmic drop that leads to an error in the measured potential differences. Molten glasses are most often highly conductive. It has been shown that an electrical resistivity lower than 4Ω has no influence on the measured potential differences.

4.2.2 Linear Voltammetry

With an inert working electrode, linear voltammetry is conveniently used to determine the electroactivity window of a glass. The same method can be used to study

the interaction of a metal with the same glass, the only difference being that the working electrode has then to be made from the metal in question. The existence of three domains can be demonstrated: active, passive, and transpassive (i.e. domain presenting corrosion phenomena at potentials higher than for the passive domain). Linear voltammetry is destructive since a large potential domain scanning modifies the surface state of the material.

4.2.3 Corrosion Potential and Polarization Resistance

The most basic electrochemical measurement is the corrosion potential (E_{corr}), which characterizes the active or passive state of the alloy and determines the reactions that may occur at the metal surface by comparison with the formal potentials of the redox couples (identified here with the standard potentials of the redox couples) present in the metal and in the glass. Experimentally, it is the open-circuit potential taken by a metal (i.e. the working electrode) under given conditions of temperature, glass and atmosphere compositions, etc.

The polarization resistance R_p is another important parameter, which can lead to the evaluation of the corrosion rate thanks to Stern–Geary method. Its measurement requires an additional counter electrode. A potential difference is applied between the working electrode (analyzed material) and the reference, as the counter electrode is used for current measurement. The working electrode is polarized around the corrosion potential (for example, from $E_{\text{corr}} - 10$ mV to $E_{\text{corr}} + 10$ mV). The calculation of the slope of the current vs. potential plot leads to the determination of R_p according to

$$\frac{1}{R_p} = \frac{di}{dE} \quad \text{at } E = E_{\text{corr}}, \quad (4)$$

where i is the current. By taking into account the number of electrons involved in the anodic and cathodic reactions, the kinetic parameters β_a and β_c are derived from

$$\beta_a = \frac{2.3RT}{\alpha_a nF}, \quad (5)$$

$$\beta_c = \frac{2.3RT}{\alpha_c nF}, \quad (6)$$

Figure 6 Sketch of a working electrode for corrosion characterization of metals and alloys.

Here n is the number of electrons involved and α_a and α_c are the charge transfer coefficients of the anodic and cathodic reactions, respectively (with values ranging from 0 to 1, which is generally taken equal to 0.5 in a first approximation). The corrosion current (which is directly proportional to the corrosion rate) is then obtained from the Stern–Geary relation

$$I_{\text{corr}} = \frac{\beta_a \beta_c}{2.3(\beta_a + \beta_c)} \times \frac{1}{R_p} = \frac{B}{R_p}. \quad (7)$$

Finally an order of magnitude of the corrosion rate is given by Faraday's law

$$v_{\text{corr}} = \frac{I_{\text{corr}} t M}{n \rho F}, \quad (8)$$

where I_{corr} is the corrosion current (A/cm^2), t is time (s), M is the average molecular weight of the alloy (g/mol), and ρ is the average density (g/cm^3).

The measurement of both corrosion potential and polarization resistance as a function of time is an indicator of the evolution of the system. This technique is commonly used for the corrosion of superalloys by molten glasses. It allows the choice of adapted materials to be optimized under defined conditions according to their chemical composition, morphological properties, surface condition, etc.

4.2.4 Electrochemical Impedance Spectroscopy

Understanding the corrosion mechanisms and interpreting them in terms of diffusion, oxide layer formation, and charge transfer processes is another important goal. The electrochemical impedance spectroscopy (EIS) technique is well suited for this purpose, although few studies have yet been performed with it for molten glasses.

The impedance measurement can be performed under different conditions. The potential can be the natural potential of the alloy in the melt. Under these conditions, the alloy can be in active or passive state. As a consequence, interpretation of the impedance measurements must take into account the initial condition of the alloy surface. It is also possible to impose a potential, for example, to reach phenomena occurring when the alloy is in the transpassive state, at high potentials.

Much information can also be gained from Nyquist and Bode representations [12], i.e. plots of $-\text{Im}(Z)$ vs. $\text{Re}(Z)$ and of modulus and phase vs. $\log f$, respectively, on parameters such as the resistance of the electrolyte (R_e) or the charge transfer resistance (R_{ct}). The impedance loops (Nyquist representation) are attributed to charge transfer reactions in the alloy or in the formed layers, depending on their frequency range.

5 Corrosion of Metals and Alloys by Molten Glass

5.1 Corrosion of Pure Metals

5.1.1 Noble Metals

To date, platinum and platinum alloys are extensively used in the glass industry thanks to their very high resistance to corrosion and erosion. Platinum is, for instance, used for melting pots, coating of melting vats, stirrers, and other ancillary equipment. Its high-temperature mechanical properties become limited above 1200°C , however, because of low creep resistance and recrystallization, which makes the penetration of the molten glass possible along the boundaries of the growing grains and, thus, causes degradation of the material.

Furthermore, Pt alloys can react in reducing atmospheres with metallic or semimetallic elements to form low melting point compounds [13]. Under reducing conditions, species such as Te^{IV} can be reduced to metallic state because the potential of the molten glass (-0.5 V) becomes lower than the formal potential of the $\text{Te}^{\text{IV}}/\text{Te}^0$ couple, namely, $E_f(\text{Te}^{\text{IV}}/\text{Te}) = -0.35\text{ V}$ (Figure 3). By reaction with platinum, tellurium then forms an alloy with a eutectic temperature lower than 900°C , thereby causing fast degradation of the material (Figure 7).

Platinum also undergoes catastrophic corrosion in a molten glass when it is coupled with other metallic substances such as nickel-based superalloys. Galvanic coupling not only increases the corrosion/oxidation of metallic alloys but also induces more damages in

Figure 7 Effects of tellurium reduction on platinum stability in argon atmosphere as seen on backscattered electrons micrography. (a) Pt sample immersed in a waste glass containing TeO_2 . (b) Higher magnification of the micrograph of Pt–Te eutectic grain boundary.

platinum. The reason is that, as described for reducing conditions, reduction of oxidized species of the glass (Si^{4+} , Mo^{6+} , P^{5+} , etc.) to a zero degree of oxidation takes place on the platinum surface where compounds with low melting points form.

5.1.2 Common Metals

Particular attention has been paid to Fe, Co, Ni, and Cr [5, 11] because of their presence in the cobalt or nickel-based superalloys mainly used in the glass industry. Their corrosion in a soda-lime-silicate glass has been studied with thickness-loss measurements and electrochemical methods. For Cr, the existence of a wide passivation plateau with very low current densities ($\sim 0.4 \text{ mA/cm}^2$) has been observed (Figure 8). The ability of Cr to build a protective chromia (Cr_2O_3) layer when imposing a potential lying in the passivation domain (from -900 to 0 mV according to Figure 8) demonstrates the possibility of using Cr as a protective component of superalloys in molten glasses. By contrast, the oxide layers that can form at the metal/glass interface with Fe, Co, and Ni are not protective.

When compared with thickness-loss measurements, electrochemical methods offer the possibility of identifying the corrosion mechanisms. This feature is of great importance since it opens the way to improving the corrosion resistance of metallic materials. In addition, the corrosion rates calculated from polarization curves are close to those determined from thickness-loss measurements [5]. Data obtained by electrochemical methods, therefore, can be used as semiquantitative indicators to classify metals and alloys according to their resistance against corrosion in molten glasses.

5.2 Corrosion of Alloys

In a hot corrosion context, Ni-based superalloys with a high Cr content and Al as an alloying element are a priori the best candidates for high-temperature applications (e.g. heating elements, gas turbine engines, etc.). The reason is that both metals have long been known to form at their surface the thermodynamically stable oxides Cr_2O_3 and Al_2O_3 .

5.2.1 Alumina-Forming Alloys

Corrosion of alumina-forming alloys in molten glasses is poorly documented in the literature. A recent study [14] has shown that upon raw immersion in molten glass, these alloys remain in the active state. An important Al loss is also observed. A preoxidation treatment does not improve the corrosion resistance. Indeed, according to the potential measurements, the alumina layer dissolves in the melt in a few minutes. This result is in accordance with the well-known high solubility of Al_2O_3 in oxide melts [15], which thus prevent alumina-forming alloys from being used as a high-temperature glass contact material (Figure 5c).

5.2.2 Chromia-Forming Alloys

In contrast, chromia-forming alloys are often used in the glass industry. As examples, they serve as construction materials for processing pots and susceptors in metallic melter pot furnaces, as well as electrodes in Joule-heated ceramic melter pots used for the elaboration of radioactive waste-containing glasses. Considering that the passive state can be obtained for pure chromium, similar studies have been devoted to chromia-forming alloys. For example, the corrosion of $\text{Ni}_x\text{-Cr}_{(1-x)}$ alloys, with $0 < x < 1$, in a soda-lime-silicate glass (with low MgO , Al_2O_3 , and Fe_2O_3 contents) is characterized at 1100°C

Figure 8 Passivation plateau of chromium seen in anode polarization measurements at 1050°C in an industrial soda-lime-silicate glass, contrasting with the sharp variation observed for iron, cobalt, and nickel. Inset: photomicrograph of the chromia protecting layer formed.

by important corrosion currents higher than 3 mA/cm^2 . A low Cr content in the alloy is not sufficient to build a protective oxide layer. On the contrary, a high Cr content induces spallation of the layer caused by the development of compressive stresses that result from the significant thickness of the forming chromia layer.

Di Martino et al. [5] have extensively studied the corrosion of Ni-based and Co-based commercial superalloys with chromium content as high as $\sim 30 \text{ wt } \%$ in borosilicate glass melts at 1050°C . Their results for a superalloy preoxidized or not immersed in the molten glass are compared in Figure 9. Direct immersion of the alloy spontaneously causes a corrosion that is characterized by a low potential (E_{corr}). When the alloy is in active state, the initial potential is low ($\approx -1.2 \text{ V}$, the oxidant being Si^{4+} ; Figure 3), and an anodic peak (here $I = 2.9 \text{ mA/cm}^2$) is followed by a wide passivation plateau with relatively low current densities ($I \approx 0.5 \text{ mA/cm}^2$). In the active state, the measured R_p values are close to $10 \Omega \text{ cm}^2$, which represents corrosion rates ranging between 15 and 35 mm/yr [5].

One can protect the Cr-containing alloys against active corrosion by performing a preoxidation treatment in air prior to the immersion of the alloy in molten glass (Figure 5e). This treatment “helps” the alloy to build a compact and adhesive chromia layer at the metal–melt interface that prevents direct contact between both phases. As a consequence, the alloy is directly in the passivation region characterized by a high corrosion potential ($-0.4 \text{ V} < E_{\text{corr}} < -0.1 \text{ V}$) and a high polarization resistance ($200 < R_p < 800 \Omega \text{ cm}^2$). These values point to

a corrosion rate of about 2 mm/yr, that is to say, one order of magnitude lower than that determined for an alloy in the active state. After several hours of immersion of a Ni–30Cr alloy in a silicate melt at 1050°C , a $3\text{--}5 \mu\text{m}$ thick chromia layer remains present at the metal/glass interface. This oxide layer is at the origin of the alloy passivation, preventing glass penetration and lowering the corrosion rate.

A 20–30 wt % Cr content in the alloy is thus required to develop a protective chromia layer. Nevertheless, depending on physicochemical conditions (temperature, melt composition, etc.), this chromia layer would not develop spontaneously in a molten glass, so a preoxidation step would be necessary to favor its formation at the metal/glass interface. Even though chromia-forming alloys show great potential since the solubility limit of chromia is one of the lowest among oxides [9, 14, 15], one must keep in mind that oxide growth always competes with dissolution in a molten glass: if the latter prevails over the former, the alloy will of course not be protected against glass corrosion.

5.3 Temperature Effects

These relative roles of oxide growth and dissolution depend on temperature. A transition from the passive to the active state of a Cr_2O_3 -forming alloy is shown by measurements of the electrochemical parameters E_{corr} and R_p as a function of the molten glass temperature [11]. At low temperatures, a chromia layer first develops at the metal/glass interface and ensures passivation of the

Figure 9 Anodic polarization curves of Co-based alloy in borosilicate glass for active and passive states at 1050°C . The interpretation of the curves is supported by the SEM micrographs for both conditions.

superalloy indicated by high E_{corr} and R_p values. With increasing temperatures, the alloy then proceeds to the active state upon drastic decreases of both R_p and E_{corr} . Whereas formation of the Cr_2O_3 layer is rate limited by diffusion of chromium from the metallic substrate and of dissolved oxygen from the molten glass, its dissolution is controlled by the solubility of Cr_2O_3 and the diffusion of Cr species in molten glass.

6 Perspectives

In any application, glass/metal interactions involve many individual processes. Studies of simplified systems will allow the effects of many physicochemical parameters (e.g. viscosity, basicity, etc.) to be determined individually. Likewise, the different elemental processes involved in corrosion mechanisms should be taken into account, and their kinetic contribution to the overall process should be estimated. Predicting the growth and dissolution of chromia layers as a function of temperature and alloy and melt compositions is, for instance, one of the main challenges for future developments. A predictive lifetime model could then be set up and applied to many applications, for example, the corrosion by CMAS-like glasses in aeronautical applications, the production of float glass, the sealing of solid oxide fuel cells stacks, etc. For this purpose, specific experimental and characterization methodologies need to be designed for each application. For corrosion by molten glass, electrochemical techniques are particularly adapted. They should be developed.

1 Introduction

Chemical inertness is one of the key properties that has rendered glass so valuable two millennia ago when the invention of blowing made glass vessels of any size and shape commodity products in the Roman world (Chapter 10.3). As clearly shown by the marked iridescence commonly seen on ancient glass pieces, however, inertness was not absolute. Of course, one could rightly invoke the very long periods of time elapsed since their production to account for their superficial alteration. Under a variety of circumstances, it nonetheless happens that even modern products can suffer from an alteration strong enough as to make them valueless.

Problems caused by the reactivity of glass in wet environments are thus as old as glassmaking. They have long been rather well known, so industrial glass compositions have been optimized to satisfy many requirements, among them, the hydrolytic resistance needed for the intended use as exemplified by glasses used as containers in pharmacy (Chapter 7.7). As a rule, the problems stemming from glass alteration mainly occur instead under “unusual” storage or transportation conditions. Other corrosion occurrences are related to extreme conditions. Cases in point are those found in dishwashing machines where aqueous corrosion at relatively high temperatures may be favored by the detergents used together with rinsing and brightening agents.

In this chapter the basic alteration mechanisms in acidic and basic media will be first described. The specific problems raised by soda–lime, lead-crystal, or borosilicate glasses under their conditions of use will then be briefly mentioned. Next, attention will be paid to the

problems affecting flat and container glass during storage and transportation under confined conditions. Finally, solutions to this problem will be presented. By focusing on practical problems, this chapter may be considered as an introduction to the following one where corrosion mechanisms are reviewed in detail at the atomic scale.

2 Chemical Processes and Parameters

For all types of glasses, two chemical processes cause the initial modification of the material surface in contact with the aqueous solution. Their relative importance strongly depends on the pH of the medium [1–3].

2.1 Neutral or Acidic Media

In an acidic or neutral environment, a cation-exchange reaction takes place between network-modifying cations – sodium and calcium in soda-lime silicates – from the glass surface and the hydrated H^+ ions of the solution according to the reaction

With the exception of very pure vitreous silica, which lacks network-modifier cations, any glass exchanges ions as described by Eq. (1). This first reaction produces a hydrated dealkalized layer on the surface (Figure 1), usually called a *leached* layer, whose thickness is usually too small to affect the properties of the product. As an example, the dealkalized layer is about 100 nm thick in champagne bottles having been filled with wine for many years [4]. This thickness is nearly constant in the whole area in contact with the wine and indeed too small to compromise the properties of the bottles.

Figure 1 Cation exchange described by reaction (1) at the surface of a soda-lime silica glass as revealed by the contrast between the concentration profiles of SiOH and Na and Ca observed after water attack and rinsing.

The leached layer passivates in some way the glass surface as its presence decreases the rate of penetration of H^+_{aq} ions. Its growth kinetics (Figure 2) is typical of a diffusion-controlled mechanism because its thickness increases as the square root of time [5]. It is often described as a “gel layer” because its main component is SiO_2 -containing silanol groups SiOH. On the other hand, the high solubility of alkali cations in aqueous solutions makes them easy to be “missed” if the sample is rinsed before examination. Without rinsing either by the surrounding solution or by rain or any other external action, however, the alkali cations extracted from the glass are in general adsorbed or simply remain in the leached layer. As described below, this observation is consistent with reactions of the glass surface with atmospheric CO_2 or SO_2 .

Figure 2 Diffusion-controlled nature of the alteration reaction (1) demonstrated by the linear relationship between the thickness of the leached layer and the square root of time (Source: From [5]).

2.2 Basic Media

In a basic environment, the alteration reactions are a little more complex because they involve the fragmentation of the silicate network and not a simple exchange of network-modifier cations:

Adding these two reactions, one describes the hydrolysis as

Reaction (4) takes place only when the pH is higher than 9 or 10 (Figure 3). It indicates that the OH^- ions are not consumed, but act as a catalyst causing the reaction to proceed linearly with time in the absence of the passivation layer that forms under acidic conditions (Figure 4). Then, the collapse of the silicate network can cause an irreversible alteration of the glass surface. Especially if it is spatially heterogeneous, this collapse modifies glass properties – optical, in particular – but sometimes mechanical as well. Owing to its intrinsically basic nature, cement, for instance, gives rise to an interaction with glass that is described in this manner [6].

2.3 Evolution of Water Attack: From Reactions (1) to (4)

The “basic” reaction (4) may also be considered as a continuation of the *acidic* reaction (1) because consumption of the H^+ ions of the initially neutral or slightly acidic solutions causes the pH increase required to trigger it. For this evolution to occur, however, the ratio between the area of reacting glass and the volume of the solution must of course be high. This condition excludes not only open systems but also glass immersed in a solution whose pH will very rarely become basic. Hence, it mainly applies

Figure 3 The very strong sensitivity to pH of the solubility of silica glass in an aqueous solution at 80 °C [1].

Figure 4 Effect of solution renewal on the dissolution kinetics of a soda-lime glass in a basic $N/2$ NaOH solution [3]: (1) 90 ml every 30 minutes; (2) 10 ml every four hours; (3) no renewal base line.

to products submitted to a confined, moist atmosphere such that the volume of water is actually small compared with the glass surface area.

As a matter of fact, after processing, the reaction can begin as soon as industrial products are submitted to a naturally wet atmosphere because the surface of alkali or alkaline earth aluminosilicates gets covered at room temperature by a very thin water layer at relative humidities as low as 30 % [7]. The process originates in the polar nature of the water molecule, which makes van der Waals bonding possible with a variety of high-energy surface defects such as low-coordinated charged silicons or isolated nonbridging oxygens. As a result of Eq. (1), the process yields OH groups on the surface, which are themselves covered with water molecules linked by van de Waals bonds. The water layer thickness depends on the partial pressure of water vapor (Figure 5). Even if water condensation is not visible on the glass surface, it follows that reactions between glass and water are nearly always possible. Museum rooms kept under controlled atmospheres are no exceptions.

3 Alteration as Related to Glass Composition

3.1 Soda-Lime Glass

Whether as flat, container, or even insulating fibers, glasses of the soda-lime family are by far the most commonly produced. Fundamentally their alteration originate in the relatively weak bonding of Na^+ ions to the silicate network as made obvious by the fact sodium-rich binary silicate glasses are highly hygroscopic: they would

Figure 5 Average number of layers of molecular water on the surface of various glassy or crystalline oxide substances as a function of relative humidity [7].

simply disappear over rather short periods of time without the addition of calcium. But CaO is a poor flux compared with Na_2O , so increasing further the content of the less mobile Ca^{2+} ion to improve chemical durability [8] would end up in an enhanced devitrification tendency upon melt cooling.

Without this problem, in contrast, the introduction of 0.5–3 wt % Al_2O_3 in the composition notably increases glass durability [9]. Possibly a modification of the structure of the leached layer is involved, as suggested by Al_2O_3 contents that can reach 15 wt % in this surface layer. A second factor is the decrease of the content of network-modifier sodium ions resulting from their charge-compensating role for Al^{3+} in tetrahedral coordination (Chapter 2.4). At first sight such a decrease might seem too small to translate into significantly improved durability, but it is unlikely fortuitous that similarly small amounts of Al_2O_3 cause metastable immiscibility in the Na_2O-SiO_2 system to disappear [10]. One may thus surmise that introduction of small amounts of Al^{3+} results in a more homogeneous distribution of sodium in the overall structure, which makes H^+ ions less readily exchangeable for Na^+ .

3.2 Lead-Crystal Glass

At PbO contents higher than 24 wt %, lead-crystal glass presents a correct resistance to water hydrolysis, but it is more sensitive to corrosion in an acidic environment. Some lead can then be released in solution when drinking glasses and decanters contain liquids such as wine [11]. Regulating authorities have thus imposed leaching tests with a 4 % acetic acid solution for 24 hours at 22 °C [12] during which the amount of lead released must be lower than 5 and 2.5 mg/l for containers with a capacity of less and more than 600 ml, respectively. If the amount of lead released is greater than these values, either the composition of the glass must be modified to improve

its durability or the inner surface of the container must be treated to decrease the lead concentration in the first atomic layers so as to minimize further release upon use. The former procedure involves increases in SiO_2 , reduction of alkalis or addition of trace amounts of MgO or ZnO , and the latter acid polishing, ammonium sulfate fuming, or deposition of coatings [13]. That acid aging prior to use is an efficient manner to reduce subsequent lead leaching agrees with analyses performed on 24 % PbO lead glass decanters after 10 or 20 years of continuous use, which have confirmed that the process is self-limiting exponentially as a function of the distance from the glass–liquid interface [14]. This is the reason why crystal-glass manufacturers usually recommend to fill before use a new crystal-glass container with vinegar for 24 hours and then to rinse it thoroughly.

3.3 Borosilicate Glasses

Commercial alkaline borosilicate glasses (Pyrex® type) are well known for their high durability [15], which results from stabilization of alkali cations through charge compensation of tetrahedral boron (Chapter 7.6) and, in phase separated glasses, by the stable silica-rich matrix within which the phase rich in alkali borate is dispersed. The absence of alkali cations free to migrate into water from the surface yields a glass nearly as stable as silica glass, except in basic environments, which makes them in pharmacy the best containers for drugs (Chapter 7.7).

Other compositions of this type of glass are commonly used for vitrification of nuclear waste for very long-term storage (Chapter 9.10). In this particular case, the dissolution of the glass matrix nearly stops when the maximum solubility of silica in the surrounding medium is reached and a condensed protective layer forms. But this step is never encountered in common uses of ordinary commercial glasses.

3.4 Insulating Glass Fibers

With basically soda-lime compositions, to which a few wt% B_2O_3 are added, glass wool is closely related chemically to soda-lime silicate glass (Chapter 9.3). Its alteration thus conforms to the above description. The major difference concerns the extremely high specific surface area of glass wool. If these fibers are immersed into water, the pH immediately increases to values higher than 10.5 because of the very fast leaching of alkali cations made possible by the extremely high ratio between glass surface area and the volume of the solution. The attack may thus be very rapid if the product is not protected against water vapor condensation.

Insulating glass fibers called rock wool are more resistant because they contain large amounts of alumina and

less sodium oxide (Chapter 9.3). Nevertheless, their specific surface area is very similar, so potential problems related to the pH increase are only delayed.

3.5 Reinforcement Fiberglass

The typical E-glass used for those applications is a calcium aluminosilicate containing less than 1 wt % of Na_2O (Chapter 1.6). The sizing covering the fibers is in principle efficient against water penetration. Corrosion nonetheless can take place through interaction with acidic species that would be present in the immediate vicinity of the fibers. Calcium, aluminum, and boron are then extracted, potentially inducing a loss of mechanical properties.

4 Post-Production Corrosion of Flat and Container Glass

4.1 Flat Glass

The composition of soda-lime glass has only changed marginally ever since it was produced at a really industrial scale two millennia ago in furnaces of up to 20-ton capacity (Chapter 10.3). Empirically, it had already been found that what we now term the eutectic region of the Na_2O – CaO – SiO_2 system was ensuring not only the lowest temperatures for melting and chemical homogenization but also the appropriate long-term durability with respect to rain and other atmospheric agents. Under usual climatic conditions, the thickness of leached-glass layer is smaller than 100 nm [16] because the corroding solution in contact with the glass surface keeps renewed, so the pH remains neutral.

In the modern world, however, this condition is not necessarily satisfied upon glass storage or transportation where efforts are made to save as much space (and air) as possible. For flat glass, the surfaces of the panels are, for instance, kept apart with *spacers*, usually polymer powders having a grain size of a few tens of microns. If water penetrates in between the panels, most frequently through condensation, then the ratio between the glass surface area and the volume of the aqueous solution can become very large, so the pH increases until reaction (4) begins. The leached layer has a different composition and, thus, a different refractive index. If its thickness reaches a fraction of 1 μm to become commensurable with the range of wavelengths of visible light, then iridescence will manifest itself as optical interferences. In addition, the attack cannot be homogeneous because water is trapped by the polymer spheres. The eye being very sensitive to optical differences, this inhomogeneous corrosion also becomes visible very rapidly through slight

light scattering. In this case, an acidic polymer may thus improve the situation.

In usual storage alteration, the chemical profile is characterized by a 100 nm-surface layer enriched in silica. Reprecipitation of silica extracted from the glass may yield a thin, very heterogeneous, and fragile, light-scattering layer on the surface. This type of defect appears faster when water condensation is coupled with high temperatures, for instance, upon shipping in tropical or equatorial areas. At a much smaller scale, the effect is similar to that observed on artifacts found in archeological excavations. This phenomenon also occurred in the early double-glazing windows within which air could circulate, but not fast enough to ensure a sufficiently low humidity content. The result was occasionally the formation of a whitish or even, in some extreme cases, crizzling layer.

When the surface modification is visible, the glass is usually rejected: Only polishing with cerium oxide could restore a satisfying surface, but the process is much too expensive to be applied to usual flat glass. Even if the modification has not yet become visible, the glass can still be useless for applications requiring treatments such as thin-layer deposition, a process commonly used today, because adhesion difficulties or problems caused by a heterogeneous aspect could occur. The precipitation of large crystals such as sodium and calcium carbonates or sulfates is less problematic when the species extracted from the surface (e.g. Na^+ , Ca^{2+}) and adsorbed in the “gel layer” react with gases present in trace amounts in the atmosphere such as CO_2 and SO_2 . For carbonates, these reactions are, for instance,

Usually those crystalline salts are simply washed out, with acidic water for calcium salts, before using the glass. Finally, a peculiarity of float glass (Chapter 1.4) should be

noted with respect to the asymmetry existing between the “tin” and “atmosphere” sides. The existence in the former of a sharp SnO_2 gradient beginning with contents of a few wt % right at the surface makes this side more durable than the latter, which in practice is the only one affected by corrosion.

4.2 Container Glass

After manufacturing, containers are gathered on pallets closed by polyethylene sheets and stored for periods typically ranging from a few days to a few months. Depending on storage conditions, water condensation can take place and cause alteration of the inner sides of containers according to reaction (1). Again, the extracted alkali and alkaline earth ions (in practice, Na and Ca) can react with atmospheric CO_2 to precipitate carbonates. Although SO_2 has a greater reactivity in this respect than CO_2 , the SO_2 partial pressure in the pallet is usually too low for sulfites or sulfates to precipitate.

Sodium carbonate crystals form as needles whose size reaches a few hundred microns, often well crystallized in a *crow's feet* pattern (Figure 6). They may be difficult to observe because a high hygroscopicity cause them to absorb so much water under a wet atmosphere that they dissolve in the form of a droplet, from which crystals can then reprecipitate under drier conditions. Owing to its small solubility of about 0.001 g/100 ml in water, calcium carbonate does not experience similar cycles of precipitation–dissolution. It forms instead small hexagonally shaped prisms that are initially about 1 μm long and become much larger when alteration proceeds (Figure 7).

Analyses of the glass underneath the altered zone or after light-acid washing shows that the glass surface is indeed depleted in Na and Ca. The optical aspect is slightly modified by a thin light-scattering layer that is not easily observed when the glass is colored. After

Figure 6 Effect of rinsing on the inner surface of a soda–lime bottle after a one-year outdoor storage as seen in SEM micrographs (2000 $\times$ magnification). (a) Before rinsing: presence of both Na_2CO_3 and CaCO_3 . (b) After rinsing: only CaCO_3 left.

Figure 7 Optical micrography of large CaCO_3 crystal present on the inner side of a bottle stored one year without rinsing (magnification 200).

filling of the container, sodium and calcium salts dissolve because of the slight acidity of the content, and the veil thus completely disappears. But carbonate crystals can act as nucleation sites for bubble formation in the case of carbonated beverages, which then causes filling problems.

Under the adverse conditions, for instance, found in warm climates, one can observe below the CaCO_3 crystal holes of a similar dimension that signal a localized attack of the glass surface. As these crystals are especially insoluble, their presence as solid deposits on the surface can induce condensation of water if the relative humidity is high enough. The very basic pH locally induced by the process [17] generates defects that cannot be removed by an acidic treatment. This kind of extreme alteration was also observed when the first dishwashing machines used high-pH salts at high temperatures during long washing cycles. The attack was often nonuniform as a result of variations of chemical composition in the glass surface. As resulting from contact of the glass with the forehearth refractories, local Al enrichment leading to a reduced alteration could then be observed.

This type of chemical alteration can be found within containers but not on flat glass despite its lower hydrolytic resistance. This could be explained by the formation of sulfates on flat glass, instead of carbonates in bottle glass.

In the specific case of pharmaceutical bottles, besides the cations released, the porosity of the surface layer resulting of the attack can induce adsorption of molecules from the content on the internal wall of the container, thus the necessity of the treatment for this type of use (cf. Section 6). The external side can also present such phenomena, but the problem is less severe for two reasons. The first is that it does not have any consequence on the content of the container. The second is that this external side is usually covered with a thin protective tin (or titanium) oxide + polymer (PMMA) film (Chapter 1.5).

5 Characterization Methods

A brief summary of the various normalized tests devised to determine commercial glass durability is presented in Table 1. Apart from those normalized methods, other tests can be applied, especially to flat glass, in environmental climate chambers reproducing alternating humidity and temperature conditions. For practical purposes, a temperature increase of 10°C is considered to yield roughly a twofold increase of the alteration rate as a whole. This rule of thumb is of course approximate as reactions (1) and (4) have different activation energies, which should not be forgotten when corrosion tests are performed at temperatures higher than those of use to determine the durability of a glass. One must also keep in mind that the ratio between the surface area of the glass and the volume of the solution is the fundamental variable for the switch from reactions (1) to (4).

In addition to chemical analysis, it is essential to determine the species leached out of the glass surface after the test and to study the chemical modifications induced by the alteration. Various methods exist for such surface characterization, such as scanning electron microscopy,

Table 1 Summary of some tests made to determine glass durability.

Reference	Medium	Type of glass	Surface or bulk ^a	Temperature ($^\circ\text{C}$)	Time (hours)	Measurement

^a Bulk usually means that the glass sample is ground to a definite grain size so as to know accurately the surface area before testing.

but mainly secondary ion mass spectrometry that allows concentration profiles to be measured with a resolution of a few nanometers (Chapter 2.3). When the attack is severe enough, the scattering of light observed in optical measurement can yield a good qualitative idea of the glass alterability.

6 Protection Methods

The most obvious way to protect flat or container glass against water corrosion is to keep it from variations of temperature and humidity during storage before use. But this is not always possible, especially for flat glass, which is subjected to longer travel times than containers whose rather low value makes long-distance transportation uneconomical.

Two solutions have thus been adopted by flat glass-makers, namely, deposition of a thin layer of a weak acid like adipic acid $[(CH_2)_4(COOH)_2]$; the precursor in nylon synthesis, which keeps the pH of the medium at low values; or pulverization at the surface of a Zn^{2+} -bearing solution. Although the actual mechanism by which the glass surface is protected by Zn^{2+} is not well understood, the effect results in a three- to fivefold time increase of safe storage.

For either pharmaceutical containers in contact with drugs or lead-crystal glass in potential contact with food or beverages, the hydrolytic resistance of the glass can be increased by up to 10 times if a dealkalization treatment is applied at high temperature. Referring to Chapter 7.7 for the former case, it will suffice here to state that several methods can be used [18]: dealkalization by ammonium sulfate, difluoroethane, or simply SO_3 . At high temperature (550–600 °C), sodium is extracted from glass and combines with the gas to give

On the surface of the glass, this reaction forms a few hundred-nanometer-thick layer, having a composition close to SiO_2 , which acts as barrier to sodium migration and block the advancement of reaction (1) at a negligible level.

7 Perspectives

Although modern industrial products do not often present visible alteration, glass is far from being chemically inert. It is not rare to observe modifications of its chemical composition within a surface layer of about 0.1 μm driven by the mobility of alkaline cations and their

exchange with protons coming from aqueous solutions. This modified layer is sufficient to make thin-film deposition difficult on flat glass, which has induced glass manufacturers to store newly produced pieces in controlled temperature shops and/or to reduce the storage time before coating, for instance, or making protection treatments, without completely eliminating the problem.

Modifications of the chemical composition of the glass through alumina addition has quite a large effect although this influence has not yet been completely explained. The probable reason is that Al_2O_3 accumulates at the surface in a hydrated form along with SiO_2 and so plays a role on the reorganization of the surface layer and on the diffusion processes through it. This layer being very rich in water, its examination under vacuum with usual analytical tools is not really adequate. As described in the following chapter, new methods are thus required to gain new insights on the chemical stability of glass.

Mechanisms of Glass Corrosion by Aqueous Solutions

Roland Hellmann

ISTerre, CNRS, Université Grenoble Alpes, 38058 Grenoble Cedex 9, France

1 Introduction

Chemical alteration by aqueous solutions is one of the most important processes undergone by glasses, either in industrial and environmental applications (Chapter 5.11) or naturally at the Earth's surface (Chapter 7.3). Induced by the intrinsic chemical instability of glass, aqueous alteration is referred to as corrosion in a laboratory setting, or chemical weathering in nature. Chemical weathering is due to the action of abiotic or biotic agents, or both, and plays a major role in controlling seawater chemistry and aqueous CO₂ uptake during dissolution [1], for example. Industrial and environmental applications of glass corrosion include the development of durable corrosion-resistant packaging (Chapter 7.7), in situ remediation of polluted water, carbon (CO₂) capture and storage, or secure, long-term isolation of industrial and nuclear waste (Chapters 9.9 and 9.10), [2]). Archaeometry is another important field associated with glass weathering and can be used for dating of archeological glass objects and paleoclimate reconstructions [3].

Knowledge of the molecular-scale mechanisms of alteration is a prerequisite for understanding how glasses react with aqueous solutions, thereby permitting more accurate modeling of corrosion and long-term durability. Corrosion is characterized by a combination of physical and chemical processes leading to the formation of one or more surface altered layers at the expense of the pristine glass. These layers not only are primarily composed of elements derived from the dissolution of the glass, but

also typically incorporate chemical species from the surrounding bulk solution. Separating the fresh glass from the solution, this near-surface zone has a varied terminology in the literature: leached layer, gel, surface altered layer, interfacial reprecipitate, palagonite. Because the phases making up this zone are intimately associated with the chemical alteration of the glass, understanding the details of their formation is crucial to elucidating corrosion mechanisms.

Two approaches are necessary to achieve this goal: the first aims at determining the chemical composition, structure, and physical properties (e.g. porosity, pore size distribution, permeability) of the surface altered layer(s), and the second at studying the interfacial region that delimits the boundary between the pristine glass and the adjacent surface altered layer. Critical to the development of a mechanistic model are accurate measurements of the chemical and structural gradients between these two phases. For this purpose, advanced analytical techniques having very high spatial resolution, elevated mass resolution, or both, should be used.

In this chapter, the discussion of corrosion mechanisms is largely based on a historical–chronological presentation. Two early models that characterized the state of knowledge up to the mid-1980s are first described [4], followed by the traditional model based on preferential cation leaching and interdiffusion. Frequently called the leached-layer model, it combines many of the elements found in the two early models. It has held sway over the past three decades and is still the predominant mechanism in the literature. The last model treated is relatively new and is based on CIDR. Acceptance of this mechanism, initially developed in mineralogy and geochemistry, has been quite contentious but has nevertheless been gaining attention in the glass community.

List of Acronyms (cf. Chapters 2.3 and 5.1)

APT	atom probe tomography
EDX	energy-dispersive X-ray spectroscopy
CIDR	coupled interfacial dissolution-reprecipitation
EFTEM	energy filtered TEM
EPMA	electron-probe microanalysis
FIB	focused ion-beam milling
HAADF	high-angle annular dark field
HRTEM	high-resolution TEM
RBS	Rutherford backscattering spectrometry
RNRA	resonant nuclear reaction analysis
SIMS	secondary-ion mass spectrometry, including nano- and time-of-flight-SIMS
STEM	scanning TEM
XPS	X-ray photoelectron spectroscopy

2 Early Models

Dran and colleagues [4] summarized the two prevailing models regarding the aqueous dissolution of silicate glasses that held sway in the mid-1980s. The first was thought to apply to chemically complex or natural glasses. Its proponents postulated an overall congruent dissolution process, characterized by the stoichiometric release of both framework and network-modifying elements. As dissolution proceeds, the concentrations of silica and other elements build up in the bulk solution, so that upon reaching saturation, one or more secondary crystalline phases (generally silicates) precipitate onto the glass surface (Figure 1a). The alternate model was relevant to chemically simple, laboratory-produced glasses. It is based on the in situ preferential release of mobile,

network-modifying cations (e.g. Na^+ , Li^+ , K^+) into the bulk solution. Keeping the relict, leached glass structure electrically neutral requires replacement of the leached cations by H ions (most likely H_3O^+) from the bulk solution; this process may also be accompanied by the influx of molecular H_2O into the leached layer. The outer edge of the silica-rich leached layer releases Si and O to the bulk solution through chemical hydrolysis reactions (Figure 1b). Interestingly, one or the other mechanism has been used to account for the alteration of volcanic glasses, depending on their age [5].

3 Leached-layer Model

3.1 The Standard Model

The current generalized approach to glass corrosion has many similarities with the two early models. The altered zone, or leached layer, is composed of three separate entities (Figure 2). Adjacent to the pristine glass is an interdiffusion zone or layer, which is characterized by preferential removal of cations and sigmoidal chemical profiles, and is sometimes referred to as a hydrated glass layer [6]. Following this layer is a gel layer composed primarily of hydrated silica, where all the elemental concentrations are relatively constant. In the first stages of corrosion, the glass structure at the surface is progressively transformed by the selective leaching of certain cations (alkali and alkaline earth network modifiers, as well as network formers such as B) [2, 7–14]. For the interdiffusion zone to remain electroneutral, the preferentially released cations are replaced by H ions (i.e. H_3O^+) from the bulk solution. Each H_3O^+ -cation couple (e.g. $\text{H}_3\text{O}^+ - \text{Na}^+$, $\text{H}_3\text{O}^+ - \text{Ca}^{2+}$, $\text{H}_3\text{O}^+ - \text{B}^{4+}$) can be characterized by a single interdiffusion coefficient that depends

(a) Congruent glass dissolution, followed by precipitation of secondary crystalline phases on the glass surface from a saturated solution. (b) In situ transformation of the glass structure via selective cation removal by interdiffusion, characterized by sigmoidal and anti-correlated H and cation depth profiles.

Figure 2 The distinct chemistry and structure of the three layers of the leached-layer mechanism: anti-correlated chemical profiles in the interdiffusion zone, relatively constant concentrations in the amorphous gel phase, and specific compositions of crystalline precipitates at the interface between the gel and the corroding aqueous solution.

on the individual diffusion coefficients of both components. In other words, the outward diffusion rates of cations are coupled to the rate-determining (slower) inward diffusion rates of H ions. For simplicity, only two profiles representing a single interdiffusion couple are shown in Figure 2, whereas in reality there will be multiple interdiffusion profiles with different gradients and depths, depending on the charge of the cation (i.e. interdiffusion of $\text{H}_3\text{O}^+ - \text{B}^{4+}$ will be significantly slower, and thus shallower, than $\text{H}_3\text{O}^+ - \text{Na}^+$).

Throughout the process, the inner interface of the diffusive layer (the diffusion front in Figure 2) continuously advances into the glass at a rate characteristic of solid-state volume interdiffusion. This process is the same as in the early model (Figure 1b), in particular because the leached relict zone remains covalently bonded to the pristine glass via Si–O linkages [7]. The outer interface of the diffusion layer is where silica is released to solution. Because of its relict nature and the sigmoidal shape of its diffusion profiles, the leached layer should not have a sharp structural and chemical interface with the pristine glass. At a significantly higher reaction progress (ξ), a separate porous gel layer composed primarily of hydrated silica begins to form on top of the diffusive layer, mainly by hydrolysis and condensation reactions. Hence, the diffusive zone advances by interdiffusion into the pristine glass at its inner interface and is consumed by gel formation at its external interface [2, 7–9, 14, 15].

Once the gel layer has formed and continues to grow, silica is released both at the outer interface of the interdiffusion layer, as well as at the external boundary of

the gel in contact with the bulk solution. However, silica resorption can occur throughout the gel layer when aqueous silica becomes saturated in the bulk solution and within the gel pores [2]. These processes are sketched in Figure 2 as (i) inward H ion diffusion, (ii) counterbalanced outward diffusion of preferentially released cations, (iii) silica release (straight dark arrows), and (iv) silica resorption (curved dark arrows). A net balance of all these rates governs the overall thicknesses of the interdiffusion and gel layers over time. The pronounced porosity of the gel layer allows for the unimpeded inward and outward flux of reactants and products between the bulk solution and the diffusive zone–pristine glass interface. In some cases, however, eventual pore closure in the gel layer may retard the overall corrosion process [16]. Moreover, depending on the composition of the glass, alteration conditions, and composition of the bulk solution, aggregates of secondary crystalline phases (zeolites, phyllosilicates, metal oxyhydroxides, hydrosilicates) may precipitate (Figure 2) on top of the gel as a third layer [2, 7–9, 15, 17].

The attributes of this model are well illustrated in a study [9] of the three-month aqueous alteration of SON68 borosilicate at pH 8 and 90 °C (Figure 3), a chemically complex analog of the glass produced at La Hague, France, for storing nuclear waste [7]. The three different layers illustrated in Figure 2 are apparent in the chemical depth profiles (Figure 3) determined by SIMS. The leached layer consists of an inner interdiffusion zone (where sigmoidal B and Li profiles are anti-correlated with a roughly sigmoidal H profile) and an outer gel (where

Figure 3 The interdiffusion zone, gel, and surficial crystalline phases of the leached-layer model illustrated by chemical profiles measured after a three-month corrosion of SON68 borosilicate glass at 90 °C and pH 8. depleted B and Li and enriched H concentrations are relatively constant), on top of which phyllosilicates have crystallized as a porous layer. Currently, the leached layer model of glass corrosion, as exemplified by Figure 3, is the most widely accepted, in particular within the established glass community. It is the basis for nearly all codes modeling the macroscale chemical alteration of glasses in aqueous solutions (e.g. GRAAL [7]).

3.2 A Complex Hybrid Model

A major concern with most studies supporting the leached-layer mechanism is that the depths and gradients of the measured chemical profiles strongly depend on the analytical techniques used. This is illustrated by the results of a 25.75-year laboratory experiment [6], whose authors were among the first to study glass corrosion with atom probe tomography (APT), a very powerful technique that can provide three-dimensional reconstructions of the chemical and isotopic composition of a sample with subnanometer depth and lateral spatial resolution, as well as very high mass resolution ($m/\Delta m = 1000$, FWHM).

In this study, SON68 glass was altered at 90 °C and pH 7.0–7.2 in a slowly renewed granitic groundwater solution. From SEM observations, the sample consisted of the pristine glass, a hydrated (diffusive) glass layer (1000 nm), a gel layer (7500 nm), and surficial crystalline phases (a few hundreds of nanometer), yielding a total alteration thickness of approximately 9000 nm. High-resolution chemical profiles at the pristine glass-hydrated glass interface, determined by APT (Figure 4), reveal smooth decreases of Li, Na, B, and Al concentrations with increasing depth from the pristine glass interface, with gradient widths of ≈ 50 nm, and up to ≈ 100 nm for Na (Figure 4a). On the other hand, Si and H show smooth enrichment trends from the pristine glass interface, with gradient widths of 40–50 nm, whereas K (originating mainly from the granitic solution) and Ca increase over

distances of 10–20 nm and 100 nm. Much sharper gradient widths for Na and B (3–4 nm), K (5 nm), Li (17 nm), and H (20 nm) were also observed in this study (Figure 4b). Taken together, these results were interpreted in terms of a two-stage mechanism. First, an initial preferential loss of Li by interdiffusion with H occurred, which led to sigmoidal, anti-correlated Li and H profiles that became relatively constant after 15–20 nm. Subsequently, Na and B were preferentially released by dissolution, creating very sharp dissolution front profiles (Figure 4b), with strong depletion >15 nm depth.

In this hybrid model, an interdiffusion process has been combined with preferential dissolution, resulting in a steep interdiffusion front that is partially coincident in space with an even sharper dissolution front within the hydrated glass layer (Figure 5). The entire hydrated layer is by their definition a product of interdiffusion [6], but the results indicate that the diffusion profiles only extend to a depth of 20 nm from the interface with the pristine glass (Figure 4b). Diffusion modeling of leached layers [18, 19] shows that a 1000-nm thick diffusion zone characterized by a thin and steep diffusion front occupying only 20 nm at the inner extremity is physically not reasonable. In other words, the leached-layer model cannot explain how the remaining 980 nm of the hydrated layer forms, and in particular, why over the course of 25.75 years the Li and H profiles remained so sharp and so close to the interface with the pristine glass, although at the same time silica dissolution should have been occurring at the expense of the outer interface of the hydrated glass layer. Moreover, the K profile is anti-correlated with those of Na and B and mimics them in terms of sharpness and position with respect to the dissolution front. However, K had presumably diffused into the diffusive zone from the solution, a scenario that should have led to a K profile mimicking those of H and Li.

The suggestion of a hybrid diffusion–dissolution process occurring near the pristine glass interface is interesting, but whether this is physically realistic can be

Figure 4 Chemical profiles of pristine glass–hydrated glass interface obtained by APT of a borosilicate SON68 sample corroded 25.75 years at 90 °C and pH 7. (a) Profiles extending from the pristine glass to a depth of 500 nm into the hydrated glass. (b) Close up of the first 30 nm of the hydrated glass, based on original profiles (a) that were replotted with a “proximity histogram method”, producing significantly sharper elemental gradient widths. The true [B] may be lower than shown – see [6]. Source: Adapted from figure 3, [6].

Figure 5 Hybrid leached-layer preferential dissolution model [6] illustrated by a schematic partial cross section of the hydrated layer and its two interfaces (refer to previous Figure 4). (a) The 1000-nm thick hydrated glass (interdiffusion) layer is shown in its entirety. The sharp interdiffusion profiles and preferential dissolution front occupy only the extremity of the hydrated glass layer, at the inner interface with the pristine glass (20-nm thick light vertical band, drawn to scale). (b) Close up of inner interfacial region, showing partially overlapping profiles representing interdiffusion (H and Li), preferential dissolution (Na, B), and diffusive uptake (K) from the bulk solution.

questioned. In particular, this process assumes that solid-state volume interdiffusion in a glass at 90 °C is faster than competing chemical hydrolysis reactions (e.g. [20]). If true, one could ask why the diffusion and dissolution fronts would still be nearly spatially commensurate after nearly 26 years in spite of their significantly different rates. The Li ion is small and carries a +1 charge, whereas the inward diffusing, charge-compensating H species (most likely H_3O^+) is significantly larger so that it will be much slower than Li and, thus, be rate determining in the Li–H diffusion couple [18, 19]. The ultimate question is, therefore, whether the Li and H profiles represent true interdiffusion, or an entirely different process. An alternative and physically more realistic explanation of the sharp chemical gradients measured, in particular for Li, Na, B, and K, is the coupled interfacial dissolution–reprecipitation mechanism.

4 Coupled Interfacial Dissolution-Reprecipitation (CIDR)

4.1 High-resolution Analyses

Regardless of the particular manner in which chemical profiles are theoretically interpreted, a fundamental point is that the need for high-resolution data is primordial. Two types of recent experimental and analytical advances fulfill this necessity. The first involves sample preparation techniques, initially ultramicrotomy [5, 15, 21, 22] and more recently, focused ion-beam (FIB) milling [23]. Not only have these techniques allowed altered mineral and glass specimens to be prepared in cross section, but the resultant ultrathin sections (lamellae) are electron transparent and, therefore, analyzable by TEM techniques. These advances have eliminated the need to use SIMS, XPS, RNRA, RBS, or EPMA to measure chemical depth profiles. These techniques are based on successive measurements starting from the top of the surface altered layer, proceeding downward through the layer, and finally finishing in the pristine mineral or glass. More importantly, their beam footprints range from tens of μm to several mm; when applied to samples with rough surfaces and irregular internal interfaces, the ensuing chemical profiles are artificially enlarged (i.e. smeared out), making them considerably wider than they really are.

The second important advance has been the use of analytical techniques having extremely high spatial resolution (Table 1), with beam footprints in the nanometer to sub-nanometer range, to measure surface altered layers directly in ultrathin electron transparent cross sections. These techniques, primarily TEM combined with electron-energy filtering (EFTEM) and electron-energy loss spectroscopy (EELS), or STEM-EDX (scanning

TEM-energy dispersive X-ray spectroscopy), have yielded novel nanometer-scale resolved chemical maps of the interfacial region encompassing the unaltered primary phase and the secondary surface altered layer(s). Moreover, high-resolution chemistry measurements of glass corrosion by TEM have recently been complemented by the application of APT, whereas isotope tracer experiments have provided unique insights into the dynamic nature of the corrosion process.

The power of these new approaches has been demonstrated by the nm-sharp chemical and structural interfaces evidenced in altered minerals (e.g. [19, 22, 24]) and glasses (e.g. [6, 16, 21, 25–27]). Spatially commensurate chemical and structural interfaces, which are very sharp at the nanometer to sub-nanometer scale, bear none of the hallmarks of diffusion, namely, smooth and broad sigmoidal chemical profiles spanning the region between the pristine glass interface and the outer boundary of the gel [18–20]. Likewise, the formation of rhythmic and patterned alteration layers with sharp chemical and isotopic boundaries reflect chemical self-organization processes that are difficult to reconcile with a preferential cation leaching–interdiffusion mechanism. In summary, techniques such as APT, EFTEM, and STEM-HAADF have allowed researchers to gain unprecedented chemical and structural data on interfaces needed to improve corrosion models, which have in fact contradicted the majority of previous studies on both mineral and glass alteration mechanisms.

4.2 Dissolution/Reprecipitation

Even though CIDR is a relatively recent theory as applied to glass corrosion, it traces its roots back to at least 1967, when it was proposed to explain the replacement of Na feldspar by K feldspar under hydrothermal conditions. Rather than invoking the standard idea of interdiffusional coupling of $\text{Na}_{\text{feldspar}}^+ \longleftrightarrow \text{K}_{\text{solution}}^+$ to explain the formation of authigenic K feldspar, O’Neil and Taylor [28] instead postulated that “the mechanism of oxygen and cation exchange in these experiments involves the fine-scale solution and redeposition in a fluid film at the interface

between the exchanged and unexchanged feldspar.” Hay and Iijima [29] perhaps alluded to a similar process, “The sharp interface between unaltered sideromelane [a basaltic glass, see Chapter 7.2] and palagonite suggests that palagonite was formed by a microsolution-precipitation mechanism rather than by simple hydration and devitrification.” In the following years, however, this new idea was to receive scant attention in the geosciences, or other related fields, for that matter.

Further development of the theory has been marked by an intertwined history between mineral and glass studies. At least 20 years ago, researchers primarily from the geochemical–mineralogical community began to question the fundamental tenets of the traditional leached-layer model when novel experimental/analytical approaches were developed and applied to altered samples. These led to new interfacial measurements that ultimately made this change in *status quo* thinking possible. Thus, it took about 30 years after the publication of the pioneering O’Neil and Taylor study [28] for CIDR to be resurrected and further developed into a more complete theory for both mineral alteration [22, 30] and glass corrosion [21, 25, 27].

According to the CIDR mechanism, the surface altered layer (i.e. equivalent to the interdiffusion zone and gel in Figure 2) is essentially a precipitate of amorphous hydrated silica. In a superficial sense, this model resembles that of Figure 1a, which is based on precipitation of crystalline (silicate) phases from an oversaturated bulk solution. The major difference is that the *coupled interfacial* dissolution–reprecipitation mechanism is based on an interfacial process involving tight spatial and temporal coupling between stoichiometric dissolution at a sharp chemical reaction front at the pristine glass surface, and quasi-simultaneous reprecipitation within an ultrathin fluid film in contact with the same interface. In cross section, this interfacial fluid film is composed of two to three layers of ordered water molecules (thickness <1.3 nm) whose physical, chemical, and rheological properties differ from those of bulk water [31, 32]. These differences are postulated to make the precipitation of a secondary silica-rich phase on the glass surface possible, even when the bulk solution is completely undersaturated with respect to all silica polymorphs (e.g. [25, 27]).

With the CIDR mechanism, glass corrosion is initiated by local chemical disequilibrium between the pristine glass surface and the ordered water molecules of an interfacial fluid film (Figure 6a), which results in hydrolysis reactions and the creation of a sharp dissolution front. The dissolution front is characterized by the stoichiometric release of the glass constituents into the fluid film. This process eventually leads to *interfacial* supersaturation within the fluid film, causing insoluble phases to precipitate (Figure 6b). Dissolution and reprecipitation are

nearly synchronous and spatially coupled within the interfacial fluid film. The predominant phase that generally precipitates is hydrated amorphous silica, but other insoluble metal oxyhydroxides (Fe, Al, Mo, etc.) may coprecipitate (at lesser concentrations) when these metals are present in the original glass structure. On the other hand, soluble cations, such as alkalis and alkaline earths, as well as boron, have only a minimal concentration in the reprecipitated layer through which they diffuse rapidly to the bulk fluid. In fact, the relative degree of retention of elements released from the glass structure in the altered layer is largely controlled by thermodynamics (i.e., by relative solubilities).

The thickness of the reprecipitated layer of silica increases with time and depends on the net balance between dissolution–(re)precipitation processes at both the outer and inner interfaces of the surface altered layer. Whereas the dynamics of the inner interface are controlled by the interfacial fluid, at the external interface they are controlled by the bulk fluid chemistry. An important aspect of the CIDR mechanism is that there is a net molar deficit for the overall reaction, which means that more moles of material are dissolved at the glass reaction front than are precipitated in the silica-rich surface altered layer. As a result, the reprecipitate is quite porous [30], which allows for the unimpeded inward and outward flux of chemical entities (dissolution products, water, and reactants from the bulk solution) between the reaction front at the glass surface and the bulk fluid. This is indicated in Figure 6b by the arrows connecting the bulk fluid with the interfacial film. The precipitation of loosely packed silica spherules in glass corrosion layers [26] is supporting evidence for intrinsically high porosity and permeability. Pore size modification or even closure within the altered layer can occur over time [16]. Porous aggregates of secondary crystalline phases (zeolites, hydrosilicates, phyllosilicates, metal oxyhydroxides [9, 15]) may also crystallize from the bulk fluid on top of the surface altered layer, depending on the glass, bulk fluid, and alteration conditions.

Perhaps, the most important characteristic of CIDR is that the structural and chemical interfaces between the pristine glass and the reprecipitated silica are both very sharp and spatially commensurate at the nanometer scale: in other words, they are the same interface. This would be expected for a precipitated phase in contact with an underlying parent phase. Evidence for such sharp and spatially coincident structural and chemical interfaces has recently been provided for a borosilicate glass altered in deionized water for four days and one, three, and seven months [27]. In a series of STEM-HAADF and EFTEM images (Figure 7), the surface altered layer grows in thickness with time, and the boundary between the altered layer and the pristine glass remains very sharp at the nm scale. In

Figure 6 Glass corrosion by CIDR. (a) Initial stage: congruent glass dissolution in a thin fluid film comprised of 2-3 layers of ordered H_2O molecules. (b) Advanced stage: pristine glass, thin fluid film, reprecipitated layer primarily composed of hydrated amorphous silica, surficial secondary crystalline phases, and bulk solution. Soluble cations (B, alkalis and alkaline earth elements) diffuse unhindered to the bulk solution through the porous altered layer.

addition, the EFTEM chemical maps show that the altered layer is depleted in boron and enriched in silicon compared with the pristine glass and, most importantly, the chemical interface is also very sharp.

In that study [27], the one-month corroded glass was also analyzed by APT to obtain 3-D distributions of cations in the altered layer and in the pristine glass. In a 2-D view of two of these reconstructions (Figure 8a), the most interesting feature is the astounding sharpness of the chemical interface between the B- and Ca-depleted altered layer and the unaltered glass. The abrupt nature of the structural and chemical interfaces (Figures 7 and 8) is strong evidence in support of CIDR, but stands completely at odds with the leached-layer interdiffusion mechanism. Moreover, the depths of depletion or enrichment for seven cations measured by APT are all equal (≈ 50 nm, Figure 8b), even though these diverse cations carry charges ranging from +1 to +4. One of the tenets of diffusion is that cations diffuse at rates that vary inversely with charge (e.g. Chapter 4.3, and the diffusion profiles of Ref. [19]), but this is clearly violated by the results in [27]. It is also interesting to note that covalently bonded elements (network formers, e.g. Si, O, Al, B) and

more weakly bonded elements (network-modifying cations, e.g. Na, Li, Ca) show identical depths of depletion (Figure 8b), despite their fundamentally different structural roles in the glass. Taken together, these results refute a diffusion mechanism.

Other recent research also supports a nontraditional view of the corrosion process, or more precisely, the CIDR mechanism. In a recent isotope study [26], grains of a Na borosilicate glass enriched in ^{30}Si ($^{28}\text{Si}/^{30}\text{Si} = 5-8$) were altered in an aqueous solution in contact with a glass powder with a standard ratio of $^{28}\text{Si}/^{30}\text{Si} = 29.752$. A solution labeled with ^{18}O was used either for the entire experiment, or was added halfway through it. The resulting $^{18}\text{O}/^{16}\text{O}$ and $^{28}\text{Si}/^{30}\text{Si}$ isotopic profiles not only differ in the altered layer and the glass but also include rhythmic patterns and multiple peaks of enrichment as a function of depth (Figure 9). The Na profiles, on the other hand, revealed for the most part smooth depletion profiles, which might have resulted from the limited spatial resolution of the analyses. The textural interface between the surface altered layer and the pristine glass was sharp and characterized by chains of large pores. Finally, the altered layer showed evidence of spalling and flaking, indicative of very

Figure 7 Corrosion of SON68 borosilicate glass altered at 50 °C in water for increasing periods of time. On left, STEM-HAADF images of the corrosion front, the surface altered layer is delimited by arrows (scale bar: 25 nm). Center and right: ETEM maps of boron and silicon, respectively, showing B depletion and Si enrichment (scale bar: 100 nm). In each panel, C denotes carbon (from sample preparation). Cross sections prepared either by FIB milling or Ar ion thinning. *Source:* Adapted from figure 1, [27].

weak adherence (i.e. bonding) to the pristine glass substrate – this would be expected for a mechanism based on reprecipitation. In an earlier study of borosilicate glass corrosion [25], the textural and chemical data were also completely at odds with the traditional mechanism in spite of the rather aggressive conditions of the experiments (initial pH $\approx$ 0, $T = 150$ °C). In the same study, a 2500-year old naturally altered glass from an archeological site revealed a

repetitive banding pattern in the corrosion rim, which quite closely resembles the chemical profiles obtained on the laboratory-altered glass [25].

4.3 Pending Questions

Recent evidence [25–27] strongly supports the CIDR mechanistic framework of glass corrosion, which is also

Figure 8 Chemical evolution of SON68 borosilicate glass after one month of corrosion measured by APT. (a) APT reconstruction of almost atomically sharp interface between the 50-nm thick B and Ca-depleted surface altered layer and unaltered glass (each dot represents an atom). (b) Chemical profiles across glass–altered layer interface based on 3-D APT reconstructions: note sharp concentration drops of B, Li, Ca, and Na and corresponding sharp increases in Si, Al, and O at interfacial boundary. Monotonous increases in Li and Na after initial jumps due to thermal diffusion during laser pulsing. Profiles at -20 nm, from high to low concentration: O, Si, Al, B, Ca, Na, Li. *Source:* From figure 2, [27].

Figure 9 Complex chemical patterns and prevalent μm -sized porosity of silica-rich alteration layers formed during corrosion of a borosilicate glass: nanoSIMS intensity images of ^{16}O (a–c), $^{18}\text{O}/^{16}\text{O}$ (d–f), and $^{28}\text{Si}/^{30}\text{Si}$ (g–i) of glass grains enriched in ^{30}Si and reacted in ^{18}O -labeled solutions containing a glass powder with a standard $^{28}\text{Si}/^{30}\text{Si}$ ratio. Conditions: 672 hours, 90 °C, pH = 9.6. *Source:* Reprinted with permission: figure 3, [29].

consistent with the APT-measured chemical profiles in Figure 4a and b [6]. Nonetheless, the study of glass corrosion mechanisms remains controversial so that the CIDR mechanism is far from being universally accepted. One reason is the hypothesis of congruent dissolution at the glass surface reaction front; in particular, the idea that labile atoms, in particular network-modifier (or charge-compensating) cations, should be released at the same rate as covalently bonded framework-forming elements, which is perhaps counterintuitive. The CIDR model, however, does not exclude preferential ion exchange of cations with a fluid [22], as long as this process is restricted to labile atoms bonded at the *immediate* surface of the glass or mineral structure. The model does effectively preclude preferential ion exchange/release occurring deeper within the structure and the concomitant creation of a leached layer, which would invoke the (too) slow inward diffusion of reactants from the fluid. The exact mechanism of cation retention in the amorphous silica layer also merits more research. It is not known at present whether this occurs solely by coprecipitation with silica, or alternatively, by local precipitation of metal cation–oxyhydroxide phases within the nanopores of the silica layer. Cation adsorption on pore walls is another possible process. In fact, it is quite likely that all three processes occur during corrosion by CIDR.

The representation of a continuous fluid film contacting the pristine glass (Figure 6) may require refinement. This idea stems from numerous studies that have shown that altered layers are loosely bound, or even physically separated from the underlying glass [19, 26], resulting in facile detachment. On the other hand, not all studies have found evidence for spalling of the altered layer from the glass, suggesting stronger bonding. The interface might be more realistically characterized in terms of a dynamic island-fluid structure, as evidenced by chains of pores at the glass–altered layer interface [26]. Understanding the atomic nature of the interface and bonding between the altered layer and substrate glass, as well as the continuity of the fluid film, will require additional research. In particular, the use of aberration-corrected ultrahigh-resolution TEM applied to glass-altered layer interfaces may be one key to understand better how they evolve. Liquid-cell TEM (LCTEM) also shows promise as a frontier technique, as it makes possible the study of aqueous alteration of minerals and glasses *in situ* and in real time [33].

The above questions will need to be addressed in more detail in the future as CIDR is further refined. Whether or not CIDR is a universal corrosion mechanism also remains an open question, which can only be answered with more research based on cutting edge analytical techniques applied to new samples, or even to samples previously studied.

5 Rates of Dissolution and Element Release

5.1 Dissolution Rates and How They Are Measured

Aqueous dissolution data, and in particular dissolution rates, are a valuable complement to solid-state data in determining the mechanism of dissolution. The overall average long-term corrosion of glasses in aqueous fluids can be quantified in terms of total mass loss, normalized to surface area and elapsed time. However, in laboratory experiments, a far more useful quantification of corrosion is based on instantaneous rates of dissolution determined at specific time intervals. In a static reactor, the instantaneous release rate for any element i is defined as $R_i = dc_i/dt$ with units of $\text{moles}_{(i)} \text{m}^{-2} \text{s}^{-1}$. When a continuous flow-through reactor is used, the concentration of an element i measured at any given time is directly proportional to its release rate. Individual elemental release rates always need to be normalized with respect to the compositional stoichiometry of the pristine glass. Corrosion rates are commonly reported in terms of framework elements such as Si or B, depending on the type of glass undergoing corrosion.

The two mechanistic models presented in Parts 3 and 4 differ in terms of where Si release occurs. With respect to the leached-layer model, Si released to the bulk solution originates from the external interface of the gel layer and/or the diffusion zone (Figures 2 and 3). In the CIDR model, Si also has two possible sources: the fraction of Si released from the pristine glass within the thin fluid film that is not precipitated diffuses directly through the altered layer to the bulk solution; the other Si source is the external interface of the silica-rich altered layer in contact with the bulk solution (Figure 6b). In both models, the partitioning of Si release between their two respective sources is controlled in large part by the conditions of corrosion as well as the reaction progress variable.

5.2 Stoichiometry of Dissolution Rates

Glass dissolution kinetics can be quantified in terms of rates of release of network-forming cations, or alternatively, in terms of major elements present in the glass, irrespective of their structural role (i.e. network forming or modifying cations). The stoichiometry of glass corrosion is frequently reported in terms of individual cationic release rates. In acidic and circumneutral pH solutions, the normalized cation concentrations in the bulk solution are in general not equal (i.e. nonstoichiometric) when plotted as a function of time (Figure 10). Proponents of the leached-layer theory have used nonstoichiometric

Figure 10 Aqueous elemental release curves as a function of time measured during corrosion of SON68 glass. The nonstoichiometry of the normalized elemental release rates ($R_{Li} \approx R_B > R_{Cs} > R_{Si} \approx R_{Mo}$) was attributed to solubility control (i.e. CIDR) within thin fluid film at pristine glass dissolution front. These data complement solid-state results for the one-month sample shown in Figures 7 and 8. Source: Adapted from figure S4, Supp. Information, [27].

release rates as evidence for preferential release of certain labile elements coupled to incorporation of hydronium ions from the bulk solution. This is manifested by higher apparent release rates compared with that of Si, which ultimately results in the creation of a relict Si-rich leached layer (Figures 1–3). However, the aqueous data purportedly showing preferential release can alternatively be explained in terms of CIDR. In this case the intrinsic dissolution process at the pristine glass surface is congruent, but subsequent retention (i.e. reprecipitation) of released elements is controlled by each cation's relative solubility in the interfacial fluid film. Thus, soluble cations (Li, B) are preferentially released to the bulk solution, elements such as Cs with intermediate solubility are partially retained, and finally, minimally soluble elements (Si, Mo) are preferentially retained by the precipitation of an amorphous silica phase. Thus, the composition of the altered layer can be estimated by thermodynamics. The strong correlation between relative elemental solubility [34] and degree of retention within the altered layer (Figure 10) is strong evidence in favor of CIDR and not an interdiffusion-controlled leached-layer process. This example also illustrates an important point: aqueous data alone, although useful, can be ambiguous and therefore do not lend themselves to precise mechanistic interpretations. Thus, obtaining nanometer-scale solid-state data is primordial for the determination of any corrosion mechanism at the molecular scale.

As a final note, the aqueous data shown in Figure 10 were used to calculate the Gibbs free energies (ΔG) of common low-temperature polymorphs of silica (Supp. Information [27]). All ΔG values were highly negative, thereby indicating that the observed amorphous Si-rich surface altered layers (Figures 7 and 8) did not precipitate

from an oversaturated bulk fluid, but more likely represent an interfacial reprecipitation phenomenon dependent on the special properties of thin fluid films.

5.3 Dissolution Rates as a Function of Composition

Chemical composition is major factor in the corrosion of glasses. A classification of corrosion resistance of a broad range of compositions and types [35, 36] shows the following generalized glass order (with some overlap between types): soda–lime (e.g. medieval and antique glasses) < nuclear high-level waste (e.g. SON68) < natural (e.g. obsidian) < commercial (e.g. Duran, Pyrex brands) < pure silica. A general rule of thumb is that corrosion durability increases with the proportion of network-forming elements (e.g. Si, Al, B) coupled to a concomitant decrease in the abundance of network-modifying elements (e.g. Ca, Na, Li, Mg, K). The former group of elements polymerizes the glass structure, whereas the latter depolymerizes it (Chapter 2.4).

To quantify these observations in terms of thermodynamics, many studies have used an approach based on a linear free energy relation (LFER). As developed in pioneering studies [37, 38], the LFER approach allows the susceptibility of glass to hydration (i.e. aqueous corrosion) to be estimated from the weighted sum of the Gibbs free energies of hydration ($\Delta G_{hydr(i)}$) of its individual orthosilicate or oxide constituents (i). Although based on some restrictions and simplifying assumptions [35], this approach offers a good starting point for qualitatively estimating the durability of a glass. Thus, species such as SiO_2 , Al_2O_3 , CaO , Fe_2O_3 , and MnO_2 are predicted to stabilize the glass structure (positive ΔG_{hydr} values), whereas

CaSiO_3 , Na_2SiO_3 , and K_2SiO_3 destabilize it (negative ΔG_{hydr} values) [35]. There is, in fact, an inverse linear relation between $\log[\text{Si}]$ released and ΔG_{hydr} of the glass; in other words, the more negative ΔG_{hydr} , the less durable the glass and the higher the degree of Si release to solution. As a further refinement, ΔG_{hydr} can be adjusted for the solution pH to account for the dissociation of silicic and boric acids at high pH [36].

Glass composition is related to structure in terms of nonbonding oxygen (NBO) bonds, since ΔG_{hydr} correlates well with the number of NBO [37]. Hence, glass structure is usually not considered as a separate mesoscopic parameter distinct from composition. At the molecular scale it nonetheless plays a key role in glass corrosion, seemingly contradicting the preceding statement. As an example [16], it was found that the initial corrosion rate of a borosilicate glass was slowed down by substitution of zirconia (0–8 mol % ZrO_2) for silica. In the long term, however, the overall degree of corrosion increased with zirconia concentration because ZrO_2 hindered restructuring of the gel layer and, thereby, prevented pore closure. This phenomenon was deduced to be ultimately responsible for stopping corrosion by drastically decreasing the rates of diffusion of aqueous species within the gel.

5.4 Dissolution Rates as a Function of pH and Temperature

The effect of pH and temperature on glass dissolution is also quite strong and just as important as chemical composition of the glass. As has been developed and described in numerous geochemical studies for mineral dissolution kinetics, the following type of generalized rate equation for heterogeneous surface reactions [39] has also been widely applied to glass corrosion in aqueous solutions:

$$\text{Rate} = k_0 A e^{-E_a/RT} a_{\text{H}^+}^{n_{\text{H}^+}} \prod_i a_i^{n_i} f(\Delta G_r). \quad (1)$$

In Eq. (1), k_0 is the forward rate constant, A the reactive surface area, E_a the thermal activation energy of the overall reaction, R the gas constant, and $a_{\text{H}^+}^{n_{\text{H}^+}}$ the activity of H^+ raised to a power n ; the product operator term expresses the influence of the activities of other aqueous species that either catalyze or hinder the dissolution reaction; finally, $f(\Delta G_r)$ is a Gibbs free energy (or chemical affinity) term expressing the effect of deviation from chemical equilibrium on the rate, written here in a manner not based on any specific mechanism (e.g. transition state theory). By definition, $f(\Delta G_r) = 0$ at equilibrium. Many of the parameters in Eq. (1), such as k_0 , n , E_a , and $f(\Delta G_r)$, can vary as a function of temperature, pressure, pH, and other variables.

If corrosion takes place far from equilibrium and catalysis/inhibition due to other species in solution is unimportant, then Eq. (1) can be simplified and rewritten in terms of two equivalent expressions [39]:

$$\text{Rate} = k_0 A e^{-E_a/RT} a_{\text{H}^+}^{n_{\text{H}^+}} \quad (2a)$$

$$\text{Rate} = k_0 A e^{-E_a/RT} X_{\text{H}^+, \text{ads}}^{n_{\text{H}^+, \text{ads}}} \quad (2b)$$

Whereas Eq. (2a) expresses the pH dependence of corrosion in terms of the activity of H^+ , Eq. (2b) expresses it in terms of the mole fraction of H^+ adsorbed on surface sites. Both approaches are valid, but do not necessarily predict identical rates.

At any given temperature glass dissolution rates show the U- or V-shaped dependence on pH commonly observed for silicate minerals, which is not necessarily symmetric with respect to pH. As determined from regression of rate–pH data or adsorption isotherms of H^+ or OH^- , the values for n in Eqs. (1) and (2) generally range from 0 to 1 at acid pH and 0 to –1 at basic pH, where corrosion is catalyzed by H^+ and OH^- , respectively. At $4 < \text{pH} < 8$, the pH dependence is weak at most, so that corrosion rates are more or less constant (over a pH range that may be more restricted). Activation energies, derived from regression of $\ln R$ vs $1/T$ (K) data, are typically around 80 kJ/mol [34]. They are representative of hydrolysis reactions of 3-D networks of cation–oxygen framework bonds. With respect to both the leached-layer model and CIDR, an $E_a = 80$ kJ/mol increases the (Si) release rate by a factor of 20 between 25 and 55 °C. However, advance of the diffusion front into the pristine glass (Figure 2) is characterized by a significantly higher E_a , which reflects the extremely slow nature of solid-state diffusion at low to moderate temperatures [20].

5.5 Decrease of Dissolution Rates by Chemical Affinity (ΔG_r) and Pore Closure Effects

A smooth exponential decrease of release rates is observed in virtually all glass corrosion studies (Figure 10). In terms of leached-layer theory, this evolution has been split into five regimes [7] that have no precise boundaries: (i) initial diffusion (interdiffusion), (ii) initial rate, (iii) rate drop, (iv) residual rate, and (v) alteration resumption (only under certain conditions). The chemical and physical causes of the rate decrease have long been debated. In closed systems, a decrease of the $f(\Delta G_r)$ term in Eq. (1) has been commonly invoked as a result of the increasing concentration of dissolved glass species (i.e. Si) in solution. With the assumption of a rate-controlling activated-surface complex, Aagaard and Helgeson [40] calculated from transition state theory that:

$$f(\Delta G_r) = \left[1 - \exp \left(n \frac{\Delta G_r}{RT} \right) \right] \quad (3)$$

with $n = 1$ [39], Eq. (3) can then be expressed in a simpler form:

$$f(\Delta G_r) = (1 - Q/K). \quad (4)$$

Alternative relations have also been suggested, for instance

$$f(\Delta G_r) = \left(1 - (Q/K)^{1/n} \right) \quad (5)$$

with $n = 10$ [41]. In both Eqs. (4) and (5), Q refers to the ion activity product (IAP) of a given dissolution reaction, and K refers to the IAP at chemical equilibrium (i.e. solubility product).

Application of such relations to glass corrosion is problematic because a glass and a solution cannot be in chemical equilibrium since the reverse reaction will not lead to glass precipitation. Defining the Q/K ratio with respect to glass corrosion has thus been very controversial.

According to Grambow [42], dissolution of borosilicate glasses can be represented by the reaction $\text{SiO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_4\text{SiO}_4$. This approach relies on the assumption $A_{\text{glass}} \approx A_{\text{SiO}_2}$ (A denotes affinity), such that the parameter Q in Eq. (4) represents the aqueous silica concentration in the bulk solution and porous gel, and K refers to the solubility of amorphous SiO_2 . At advanced reaction progress, the buildup of aqueous silica in the bulk solution and within the pores of the gel will progressively slow down the release of Si from the external interface of the diffusion layer (Figure 2). The original hypothesis of A_{SiO_2} -controlled dissolution was subsequently modified to include the effect of water diffusion through the hydrated diffusion layer [11]: if the layer is thin and water diffusion is unhindered, corrosion can continue at elevated rates, even for chemical affinity conditions of the bulk solution close to silica saturation. The same study [11] also suggested that soluble elements (e.g. Na and B) have a “collective response” with respect to silica concentrations, meaning that their release rates decrease significantly when the bulk solution attains silica saturation.

Nonetheless, the silica-affinity model [42] has been criticized for not being compatible with many experimental observations [8]. Recent experiments on SON68 glass based on progressive addition of aqueous silica (0–150 ppm Si) have also cast doubt on its validity [43]. Even though rates decreased by a factor of 150 upon addition of Si, their pronounced nonlinear nature stands at odds with the linear decrease predicted by Eq. (4). In part because of such observations, a similar affinity model depending on the dissolution affinity of the gel layer was proposed [44]. Rather than just considering silica, it postulates that all elements in the solution and in the

gel layer determine the dissolution affinity. This approach therefore predicts that long-term corrosion is controlled by the chemistry of the bulk solution, and in particular, by secondary phases, which precipitate and thereby control ion concentrations.

Another viable mechanism accounting for decreasing reaction rates is based on the transport properties of surface altered layers. These layers have the potential to decrease the bidirectional fluxes of aqueous reactant and product species between the bulk solution and the pristine glass. Alteration layers that form upon corrosion may be intrinsically dense, or may morphologically evolve with time so as to progressively decrease rates of diffusion of aqueous species within their porous structure. It has been argued that progressive densification of the outer parts of gel layers leads to pore closure [16], which in turn significantly decreases diffusion rates within the gel layer and thereby the intrinsic rate of glass dissolution. Another study used ^{29}Si isotope tracer profiles measured on two different sample faces after 86-day corrosion experiments [45]: from the outer gel edge to the gel–pristine glass interface, ^{29}Si diffused a total distance of 950 nm (bulk solution side); on the other side of the monolith in contact with a glass powder, the gel thickness was much thinner (≈ 150 nm), and most importantly, the gel acted as a diffusion barrier to ^{29}Si , allowing penetration only over the outermost 30 nm. For closure of gel porosity to occur, and by implication a corrosion rate that becomes negligible ($R \approx 0$), the authors [45] postulated that two conditions must be met: (i) the gel must have a high Si concentration, and (ii) the bulk solution must be silica saturated. Complementary Monte Carlo simulations supported these results and showed that clogging of the porous gel occurred at the external gel–bulk solution interface.

6 Perspectives

A systematic approach is needed to study in detail the molecular-scale mechanisms that control chemical alteration of glasses in aqueous solutions. This goal can only be achieved with a methodology that goes beyond standard analytical methods that have been widely used in the past. The choice of how altered glass samples are prepared, and which analytical techniques are used, is of critical importance for obtaining data useful in deciphering the molecular-scale mechanism of alteration, as well as modeling the glass corrosion process and its kinetics. Based on published data, the decrease in long-term rates of dissolution most likely are due to chemical and physical processes working in tandem. More in-depth work will have to be done to ascertain the partitioning between

chemical and physical rate-decreasing processes as a function of time during glass corrosion.

The cornerstone for the long-term prediction of glass corrosion is an accurate understanding of the underlying mechanism(s). Therefore, employing high spatial and high mass resolution techniques to analyze surface altered phases and their interfaces with unaltered glass should be strongly encouraged for future glass studies. Moreover, corrosion experiments using isotopically labeled bulk fluids, and in some cases even labeled glasses, have already shown their enormous potential to provide complementary information on the dynamics of glass corrosion. When taken together, the combined use of all of these advanced techniques may allow for a long-term goal to be realized: establishing whether or not all glasses are ultimately controlled by the same mechanism of dissolution. Going even further, it may perhaps even lead to a universal mechanism that links mineral and glass alteration processes at the nanometer scale.

From a dual practical and scientific standpoint, no other material has been so intimately associated with light than glass because of its translucency (or transparency), of the isotropy of its optical properties, and of its limitless shapability. One can even wonder how the laws of optics and the fundamental properties of light could have been determined without glass (Chapter 10.10). Not only has this close association between glass and light not weakened in the modern world, but it has actually been strengthened to a point that could not have been guessed even in a narrow past. This section of the Encyclopedia will make it very clear.

This first chapter is a reminder of the fundamental concepts of optics provided by A. Clare who begins with light as an electromagnetic radiation to introduce the concepts of refraction, reflection, dispersion, absorption, and reemission and the manner in which these phenomena are put to use in basic optical devices (Chapter 6.1). The earliest man-made glasses were colored. It took a great many centuries before the transparency so closely associated with glass was eventually achieved. Purposely colored glass nonetheless never lost its great aesthetic appeal as so clearly illustrated by stained glass (Figure 1, Chapter 10.8). As reported by G. Calas, L. Cormier, and L. Galois, the quantum mechanical framework of solid-state physics makes it possible (i) to explain that coloration results from interactions of light with nanoparticles or with ions dissolved in well-defined sites of the glass network and (ii) to tailor rigorously light absorption for specific purposes in definite frequency ranges (Chapter 6.2).

Luminescence is another kind of light-matter interaction whereby an absorbed incident photon undergoes inelastic scattering to be reemitted at a lower frequency or, occasionally, at a higher frequency when another photon is, for example, involved. In the case of glasses discussed by L. Wondraczek, it is with rare earth and transition metal doping elements that luminescence has been optimized to give rise to special and visual effects or to technical applications such as laser gain media (Chapter 6.3). Certainly, the most important modern glass device in optics is the fiber for remote vision and especially for telecommunications without which the Internet would not exist. The challenges to make long-distance applications successful were immense, but J. Ballato shows how they have been solved at a rapid pace in terms of glass composition, purity, industrial synthesis, and drawing as well as in terms of the optical design itself and of the mono- or multimode nature of the signal transmitted (Chapter 6.4).

Without coloring elements, silicate glasses are transparent in the visible range. In contrast, they strongly

absorb light beyond 750 nm through the excitation of atomic vibrational modes. For infrared transmission, glasses with heavier and less strongly bonded atoms are thus needed to lower vibrational frequencies. The fluoride and chalcogenide systems whose structures and properties are examined by B. Bureau and J. Lucas are especially interesting in this respect as they present glass-forming compositions that lend themselves to the drawing and molding operations required to make use of their original optical properties in applications such as passive light guides or active fiber lasers and amplifiers (Chapter 6.5). Thanks to their photoluminescence, as then explained by J. Heo and K. Xu, rare earths in chalcogenide glasses are becoming significant elements in new active optoelectronic devices such as amplifiers and mid-infrared gain media either as doping ions or as *quantum dots*, i.e. nanocrystals whose optical properties become not only atomic-like (through quantum confinement effects) but tunable when their sizes reduce to a few tens of nm (Chapter 6.6).

The last chapters deal with the engineering of glass in up-to-date applications involving mainly – but not exclusively – light. Because light first interacts with the surface of a material, the variety of surface modifications reviewed by I. Sökmen, S. Oktik, and K. Bange, ranging from polishing and ion exchange to texturing and structuring, may enhance not only mechanical properties but also light transmission and absorption (Chapter 6.7). Various kinds of thin films deposited on glass surfaces are other means extensively used to modify glass surfaces. They are described by S. Oktik, I. Sökmen, and K. Bange, the best-known example being that of low-emissivity coating on window panes to improve thermal insulation (Chapter 6.8).

From the time of oil lamps, glass has been a major component of light appliances thanks to its transparency and rigidity. As reviewed by H. Yamazaki and S. Yamamoto, the changes from fire to electrical lighting in the late nineteenth century with the arc and then the incandescent, fluorescent, discharge, and xenon lamps and now LEDs and OLEDs have been made possible because each time the right glasses and forming processes have been made available (Chapter 6.9). The history of displays told by K. Maeda is similar: just as highly absorbant lead-bearing glasses had to be designed for the traditional cathode-ray tubes of TV sets, new alkali-free compositions with very high strain temperatures had to be developed to produce the now ubiquitous LCD, LED, and OLED flat-panel displays for which an outstanding mechanical stability is required at the high temperatures at which electronically active devices are deposited (Chapter 6.10).

6.1

Optical Glasses

Alix Clare

Kazuo Inamori School of Engineering, Alfred University, Alfred, NY, USA

1 Introduction

From the first refraction measurements made in the second century (Chapter 10.10) to the current ubiquity of optical devices exemplified by communication fibers (Chapter 6.4), optics has clearly been the scientific discipline with which glass has had the tightest ties. Today, optics in fact depends so heavily on glass that specific compositions tailored for particular applications are much too numerous to be counted. In these applications, glass plays either a passive role with respect to light, changing its path, or separating different wavelengths as done by lenses or prisms, or an active role in producing light itself as in lasers and other optoelectronic devices (Chapter 6.6). The question, then, is to know why glass – predominantly oxide glass – is the archetypical material used for propagating light and interacting with light in optical devices. To answer this question in this chapter, the basics of light–matter interactions, the properties relevant to traditional optics, and the material aspects of the glass that influence them will thus be reviewed briefly. More detailed accounts are given in standard textbooks (e.g. [1, 2]) whereas a comprehensive compilation of the physical properties of glasses and other materials relevant to optics is also available [3].

Traditional optics basically relies on the laws of reflection and refraction. The former was already known in Antiquity and the latter has long been derived from Fermat's principle of least-action. According to this principle, light takes the quickest path to propagate between any two points, which is thus determined by the relative velocities at which the media are traveled as expressed by

their indices of refraction. This phenomenological approach has been extremely important to design traditional optical components and it has the advantage of being also applicable to the refraction of acoustic waves. But a much deeper understanding of optical phenomena has resulted from the discovery made by J. Clerk Maxwell (1831–1879) that light of any wavelength is an electromagnetic wave, and then from the development of quantum electrodynamics. Since then, tailoring of glass compositions for specific applications has ceased to be an empirical exercise to take instead advantage of the new fundamental physical insights gained. In preamble, it is thus useful to present a few theoretical considerations.

As an electromagnetic wave, light is made up of perpendicular electric and magnetic fields oscillating at the same frequency. It interacts with matter in ways that are controlled by the electrical and magnetic properties of the material of interest. Both are largely determined by electrical charges and the manner in which their motion and energy depend on the oscillating fields within the material. In view of their low mass, electrons are controlling many optical properties through both their number density and the relative ease with which they can move in the material to polarize it as measured by the permittivity. Depending on whether they are bound or free, electrons, for instance, cause refraction by slowing down the speed of light or undergo more complex interactions through absorption and reflection.

Be they free or bound, electrons are usually governed by band structures, which themselves strongly depend on the type of bonding within the glass and, thus, on chemical composition. Through compositional changes, this is the reason why one can vary to a large extent the electron density and the optical properties of glasses. Traditionally, however, most of these materials are electrical insulators at room temperature so that they have a wide

Reviewers: J. Ballato, Materials Science and Engineering, Clemson University, Clemson, SC, USA
L. Wondraczek, Otto Schott Institute of Materials Research, University of Jena, Jena, Germany

bandgap and very few free electrons. Direct interaction of the oscillating electric field with electrons then is dominant. For some optical components, however, other kinds of materials are used in combination with traditional glasses to obtain a particular optical effect. If a high reflectivity is, for instance, required, metallic coatings are used because the free electrons of the metal can absorb and emit as well visible light at any frequency through their available free states. Depending upon the quality of the surface, metals can thus be very efficient reflectors of visible light.

2 Basic Features

2.1 Reflection Versus Refraction

When light hits an air–glass interface (Figure 1), it is either reflected (R) or transmitted (T_{in}) through refraction into the glass. At the second interface between glass and air, the beam T_{in} is partly reflected to be refracted again at the first interface, reinforcing R , whereas its other part (T_{out}) is transmitted and refracted into the air. Through refraction to T_{in} and inverse refraction to T_{out} , distortion is not apparent unless the glass is very thick and/or is very refractive. In the latter case, multiple reflections may occur, especially in thick glass, because reflection in an electrically insulating material depends on the refractivity difference with air, its intensity increasing with it. In short, the more refractive is the glass with respect to air, the larger the proportion of light reflected compared with that transmitted at that interface.

2.2 Angle of Incidence

A light beam traveling in vacuum consists of parallel straight lines or rays despite the fact that many sources undergo divergence. For a perfectly flat air/material interface, the *angle of incidence* is measured with respect to the normal (Figure 2). If its surface is scratched, however, then the material is hit by a light beam at many different angles so that light reflection and scattering are *diffuse*

Figure 1 Reflection and refraction of a light hitting a glass surface from the left.

Figure 2 Light reflected by a glass surface.

because they take place at a variety of angles. A very clear *specular* reflection (from the Latin *speculum*, mirror) of an image, keeping all its details, is not possible. If the beam is reflected internally, i.e. from a glass–air interface, it may be so totally depending on its angle of incidence. It is this fundamental property that allows optical fibers to guide light (Chapter 6.4) whereas many traditional optical components rely in contrast on the fact that the extent of bending of a light traversing an interface also depends on refractive index.

In traditional optics, silicate glasses prevail because of their high transparency in the visible region. If high transparency is required, then an optically smooth surface is also needed so that one may control the light rays. And since the interfacial refractive index also controls the direction of the light beam, in traditional optics often the surface and the ultimate thickness of the component are modified so as to alter the direction of the light beam at a given position on the lateral air–glass interface.

2.3 Beam Light Characteristics

The properties of the beam light of interest must also be considered to account for the extent to which a glass causes the light to be reflected, scattered, transmitted, or altered. The wavelength distribution is a first important parameter even if one deals with only the visible region, which represents the very small fraction of the total electromagnetic spectrum where the eye has a fairly high resolution; depending on a number of factors, the lower and upper limits of this region lie at some fixed values in the ranges 380–400 and 700–780 nm. Many traditional optics experiments were originally carried out with *white* light, which is a superposition of all the visible spectral colors (Chapter 10.10). The energy, and thus frequency and wavelength, is specific to each source so that light interacts with a material in a way that strongly depends on its wavelength distribution.

White lights can have different shades depending on their color distribution and intensities. Until recently, most of those used in traditional optics were emitted by heated filament or gas-discharge lamps (Chapter 6.9). To limit spatial divergence, however, the light had to be collimated between its source and the optics. With the

invention of lasers and, more recently, of solid-state light sources, spatial divergence has been much reduced but at the price of emissions restricted to specific wavelengths. Attempts have thus been made to make white solid-state emitters but they tend to favor the shorter, and not the longer wavelength end of the visible spectrum so that their shade is blue instead of yellow as in filament sources [4].

In traditional optics, the lights of filament bulbs and discharge lamps are the least and most intense, respectively (Chapter 6.9). Much higher intensities are obtained with single-wavelength laser sources whose light is amplified and does not spatially diverge but remains collimated. Although a high intensity might seem very favorable for optical experiments, it can result in unexpected effects even at wavelengths at which the material is not absorbing because impurities or weak interactions can cause the higher intensity of electric-field oscillation to give rise to higher order, nonlinear responses to the light [5].

3 Transmitted Light T_{in}

3.1 Light Refraction

As an oscillating electromagnetic wave, light does not need a medium to propagate. When it does travel through matter, the electrons present respond more directly by a reduced wave velocity to oscillations for the electric than for the magnetic field. At a given wavelength, this slowdown is measured by the *refractive index*,

$$n = \frac{[\text{velocity of light in a vacuum}]}{[\text{velocity of light in the medium}]} \quad (1)$$

As described by Snell's law (Chapter 10.10), the difference between the angles of incidence i and of refraction r on both sides of an interface (Figure 3) thus reflects a difference between the relevant indices of refraction:

$$n = \frac{\sin i}{\sin r} \quad (2)$$

On exiting from the higher-index material on the right to the same lower-index material (Figure 3), the light is refracted away from the normal where it becomes parallel to the incident ray from the other surface.

In practice, the speed in air is often considered instead of that in vacuum. Not only was refraction generally studied at interfaces involving air but, with its index of refraction of 1.003, air is similar to vacuum in its retardation of electromagnetic radiation. In contrast, retardation is particularly important in electrically insulating solid media in which, especially at high electronic densities, bound electrons respond slowly to propagate the wave.

Figure 3 Light passing through interfaces where the index of refraction is changing.

3.2 Dispersion

Although lights of all wavelengths travel at the same speed in a vacuum, they do not do so in a transparent material whose response for a given wavelength depends on its number density of bound electrons. Specifically, the speed at which the electrons can respond to move the wave through the material depends on the frequency of the oscillating field (how often it increase/decreases and changes direction) and how close to one another are the electrons. Because the frequency of the field oscillation controls the velocity reduction of the wave, it causes the refractive index of the medium to depend on frequency, even in the narrow visible range and, thus, on color. This is why each color of an initially white light is refracted at a slightly different angle at an interface. This dependence of the refractive index of a medium on wavelength is known as the *dispersion* of the material. For pure silica glass, n , for instance, decreases from 1.53 to 1.4 from 0.3 to 3.6 μm wavelengths (Figure 4). If dispersion allows the different wavelengths of a light to be separated with a prism or gratings, it also results in the *chromatic aberration* that severely limits the resolution of a single magnifying lens since for a given incident beam the different wavelengths are focused at different distances (Chapter 10.10).

As a simple way to account for dispersion in the visible range, it is customary to measure the index of refraction at three well-defined wavelengths toward the end and in the middle of the visible range. The blue F-line of hydrogen at 486.13 nm (n_F), the yellow d-line of helium at 587.56 nm (n_d), and the red C-line of hydrogen at 656.28 nm (n_C) are often selected for this purpose.

When no indication is given, the reported index of refraction is n_d , which is the one referring to the middle of the visible region. The index difference between the F and C lines is the *average* or *principal* dispersion. More

Figure 4 Index of refraction of SiO₂ glass (Corning code 7940) from the ultraviolet to the far infrared. *Source:* Input data from [6].

conveniently, the dispersion may be simply characterized by a parameter V defined by Ernst Abbe (1840–1905) in terms of the indices of refraction for red (n_r), yellow (n_y), and blue (n_b) colors, namely

$$V = (n_y - 1) / (n_b - n_r), \tag{3}$$

whose reciprocal is termed the *relative* dispersion. Along with the index of refraction, the *Abbe number* is useful for summarizing the optical properties of glasses as a function of composition (Figure 5; see also Figure 6 of Chapter 7.9). The long-standing opposition between *flint* and *crown* glasses is in particular readily rationalized in terms of V values lower and higher than 50, respectively.

An ideal optical glass would combine a high refractivity with a low dispersion. As obvious in the Abbe diagram,

Figure 5 Abbe diagram for inorganic glasses and organic polymers. WG, soda-lime silica window glass. *Source:* After [7].

Figure 6 External refraction and total internal reflection in glass. (a) Refractive index of air to glass, $n = \sin i / \sin r$. (b) Total internally reflection at the interface between a higher- and a lower-index medium.

such a combination would actually run counter the observed trend according to which a high refractive index tends to correlate with a high dispersion. The reason is that the higher electron density that can respond to the oscillating electric field, the more the electromagnetic wave slows down whereas the electric field of the light wave is similarly slowed down by the field causing charged particles – typically the electrons – to oscillate (in the same way that a moving body is more slowed down by a denser medium). The type of material, its composition, and structure thus control the number density and types of electrons (free or bound) with which the wave interacts and, hence, the oscillations caused by the field.

For an analytical description of dispersion, one usually fits a Cauchy or Sellmeier equation to the observed wavelength–refractive index relationship. The latter equation is preferred for optical glasses [8]. If λ designates the vacuum wavelength, in micrometers, its general form is

$$n^2(\lambda) = 1 + \sum \frac{B_i \lambda^2}{\lambda^2 - C_i}, \quad (4)$$

where the summation is made over the absorption resonance peaks and the fit parameters B_i and C_i represent the

Figure 7 Relationship between absorption peak and refractive index.

strengths of these resonances and the squares of their frequencies, respectively.

Particularly in the visible range, the dispersion of optical glass becomes specially strong close to an absorption frequency where the refractive index becomes very sensitive to the wavelength because it is a function of the first derivative of the absorbance (Figure 7). This index goes through zero at the absorption peak, and then steeply increases with the wavelength until reaching a sharp maximum and decreasing. As discussed below, the origin of such a dispersion in traditional optical glasses is the ultra-violet absorption edge from electrons excited across the electronic bandgap.

3.3 Light Absorption and Re-emission

The propagation of light is also affected by absorption or scatter by the medium. The wave-particle duality requires to consider light as isolated packets of waves, known as photons, for which de Broglie relation states that

$$E = h\nu, \quad (5)$$

where h is Planck's constant and E and ν are energy and frequency. If E exactly matches the energy interval between two states of charged particles within the material (usually electrons, for visible light), then the photon may be absorbed. By inducing a change from a lower to a higher energy state in the material, the photon then finds itself eliminated from the transmitted light.

Through a sample of thickness d , the intensity I transmitted is given by Beer–Lambert law,

$$I = I_0 \exp(-\alpha d), \quad (6)$$

where I_0 is the intensity of the incident light and α the absorption coefficient at the wavelength considered. As already stated, absorption can take place if the energy of the wave oscillation exactly matches an energy interval to bring an electron from a lower to a higher level in the electronic structure of the material. If there are free electrons, like in metals, these intervals are very numerous so that many photons are absorbed and often immediately re-emitted because higher-energy states have short lifetimes. For electrically insulating materials, like traditional optical glasses, any photon whose energy exceeds an analogous interval transfers part of it to an electron so that its frequency is diminished instead in the transmitted light.

For solid materials, the energy intervals depend on the electronic structure of the individual atoms, on how these are bonded, and on the overall atomic structure of the glass. In general, the band structure of the material has to be considered. As electrical insulators, most traditional

Figure 8 Absorption spectrum of window glass. Source: After [9].

optical glasses have a full valence band, a wide bandgap, and an empty conduction band. As a result, they typically absorb light only at energies higher than those of the violet end of the spectrum, which causes electrons to be excited from the valence into the conduction band over the wide gap. But many of these glasses have polar bonds, which give rise to vibrations and, thus, to absorption at infrared frequencies. By a happy coincidence, the eye is sensitive in the range where silicate glasses absorb very little between the UV and IR ranges (Figure 8). This is the very simple reason why these materials look transparent and why they have been traditionally used in optics.

But transparency may be modified, for example, by addition of colorant ions acting as filters for specific wavelengths. Typically, the absorbing ion has a low enough concentration such that it is incorporated in the network as an isolated species that keeps its distinct electronic energy levels without participating in the band structure of the glass (Chapter 6.2). As a result, color filters transmit the light that is not absorbed by the isolated ions, whose absorption coefficients vary considerably; for example, small quantities (fractions of a weight %) of cobalt oxide in glass give a deep blue color whereas similar quantities of a rare earth like neodymium oxide would give a very pale (almost invisible violet color). When promoted to higher energy levels, however, these ions tend to return to their ground state but they often do it not immediately and not directly. If the de-excitation takes place through intermediate electronic levels, i.e. at smaller energy intervals, the light emitted has a longer wavelength (lower energy). For certain ions such as some rare earths and transition metals, such a *photoluminescence* can be quite strong (Chapter 6.3).

4 Glass Properties

4.1 Bonding

In general, there are three types of primary bonding in traditional materials, namely metallic, covalent, and ionic. Most materials combine two of them, often in conjunction with secondary weaker bonding such as van der Waals.

In metals, light predominantly interacts with free electrons because, regardless of the band structure, very little energy is needed to let them oscillate. With partially filled or overlapping bands, the electronic structure of metals causes all wavelengths to be absorbed – albeit not with the same intensity – and re-emitted immediately. In traditional optics, metals have thus been used to enhance reflectivity in the form of thin polycrystalline films deposited on a glass surface. Although metallic glasses have been known for some time as ribbons or other kinds of thin samples, they are more recent in the bulk (Chapter 7.10). As a result, they have yet to make an influence in traditional optics although, if they could be made optically smooth, their enhanced corrosion resistance should be an asset to make highly reflective surfaces.

In traditional oxide optical glasses, bonding is either ionic or covalent and more typically represents a combination of the two (Chapter 2.1). The degree of covalency depends on the relative tendencies of the metallic species to give up electrons and of the nonmetal species to accept them as determined by their relative electronegativities. Two bonded species with a small or zero difference in electronegativity form a largely or completely covalent bond, respectively. If the electronegativity difference is large, the bond has an ionic character that is strong but cannot be complete.

When many atoms are present in the solid, the electron energy levels combine to form bands. In contrast to those of metallic bonds, the new atomic energy levels are usually full so that the electrons tend to be bound up in bonding. With covalent and ionic bonding, free electrons are available if the highest filled (valence) band is separated from the next highest empty (conduction) band by a gap so as to allow conduction to take place. Typically, those bandgaps are very large for solids with a predominantly ionic character. In more covalently bonded solids, they can be in contrast small enough to promote electrons to the conduction band either at room temperature or with low-energy photons.

Bonding is on average a 50 : 50 covalent ionic mix in silicate glasses, which have thus generally a large bandgap. The polarizing interactions that control the speed of light through are thus typically due to bound electrons in the material. On the short wavelength/high energy end of the spectrum, transparency is limited by the bandgap of the

material – a wider bandgap shifting transmission toward higher energies, at shorter wavelength typically in the ultraviolet spectrum. On the long wavelength end, transparency is in contrast limited by vibrational transitions of the bonds, provided their polarities make their excitation possible by the electromagnetic radiation. For most inorganic glasses, the limit to the transmission of infrared light actually depends on the strengths and masses of the bonded species, weaker bonds, and heavier bonded species allowing for longer transmission at infrared wavelengths (Chapter 6.5).

4.2 Homogeneity

Another good reason for making glass the standard transparent medium in traditional optics relates to its homogeneous, stress-free structure that can be achieved with adequate melting and annealing procedures at least at a scale larger than or equal to the wavelength of light. There is, therefore, a striking contrast with polycrystalline materials in which not only different crystallographic directions often have different light-wave velocities and refractive indices, but in which transparency is limited by reflection and refraction at grain boundaries. Wavelength-dependent processes such as Rayleigh and Mie scattering can nonetheless occur in glasses because of unavoidable structural inhomogeneity at the atomic scale. Although such processes have to be considered for optical fibers (Chapter 6.4), they do not constitute a problem for the relatively conservative path lengths of light in traditional optical components.

5 Glass Responses

5.1 Reflection

Independently of Snell's law, which rules prisms, lenses, and other optical components, changes in refractive index at an interface can also control the reflecting properties of the glass. At an interface between a low- and a high-index material, the intensity of the reflected light is greater in the latter. In a highly polarizable material, the reason is that the light is more slowed down through more interactions with oscillating electrons so that it is less transmitted and more reflected. Application of Fermat's principle to reflection then implies that the angles of incidence and reflection are the same. But whether or not one can see a reflected image depends on the aforementioned optical smoothness of the interface since roughness would result in variations of the incident and reflected angles.

In internal reflection (Figure 6), there is also an interface between the high- and low-index materials through which

refraction would take place if the angle between the transmitted light and the interface normal is larger than the angle to the same normal in the material. Since the refractive index is greater within the material than outside it, significant reflection of the light back into the glass would seem unlikely according to our previous discussion of the phenomenon. By virtue of Fermat's principle, this may nevertheless occur for a reflection angle equal to the angle of incidence to that interface. Internal reflection actually becomes significant when the angle of refraction into the low-index medium becomes 90° or higher with respect to the normal, in which case the light is wholly reflected internally. Known as total internal reflection, the phenomenon is used occasionally in traditional optics, mostly in prisms, but by far its most significant impact is its use in light transmission along optical fibers (Chapter 6.4).

5.2 Absorption

If the energy of the photons of the wave exactly equals the interval between two states of a charged particle, then the particle can transition from a low- to a high-energy state. As an obvious consequence, the number of photons of that particular energy is reduced in the light beam in a way that depends on their availability. Unless purposely doped for filtering specific visible wavelengths of light, most oxide or silicate optical glasses typically have two major fundamental absorptions to contend with that are dependent on composition. Apart from a few specialty exceptions, traditional optical glasses are not electron conductors; they have large electronic bandgaps between the upper filled valence bands and empty conduction bands. Owing to structures more disordered than those of their crystalline counterparts, glasses have less clearly defined band edges. Because of insufficient energy, however, visible light cannot enable electronic conduction through promotion of electrons across the bandgap. Only photons in the ultraviolet can do it. In this case, once the minimum energy gap is exceeded, the conduction band is wide enough to accept multiple electrons so that this energy represents more an absorption edge than an absorption peak. Hence, fewer potentially electronically conducting bonds – typically more ionic – are required for extended transparency in the ultraviolet.

At the low-energy end of the visible, it is also the oscillating electric field that interacts with the material. But in this infrared region, the energies typically couple with the vibrations of polarized bonds, which result from some ionic character associated with electronegativity differences. The frequency of the absorbed light depends upon the frequency change of bond vibrations in the glass. If bonds terminate by light elements and have a low force constant, they couple with IR radiations of lower frequencies, or longer wavelengths, which are likely transmitted

further into the infrared. Alternatively, transmission can also be achieved with a 100% covalently (nonpolar) bonded element whose vibrations do not involve polar species so that they do not couple with the electric field oscillation of the electromagnetic wave.

5.3 Glass Types for Traditional Optics

Optical glasses transparent in the visible have traditionally been made from oxides, SiO_2 being predominant. Although silica is a single-compound glass former, it tends to be used only when high purity or extended transmission into the ultraviolet is needed. The main reason is that its vitrification either requires very high melting temperatures or methods such as chemical vapor deposition (Chapter 6.4), which are both expensive. Multicomponent silicate glasses are thus usually preferred because of lower melting temperatures, easier chemical homogenization, lower viscosities, and, thus, ready casting to obtain an optically homogeneous material after careful annealing (Chapter 3.7). Specific oxides can be added to ease both melting and glass formation (typically modifiers such as alkali or alkaline earth metal oxides) and to tailor the refractive index (typically high polarizability ions such as lead), absorption (such as transition metal oxides) or photoluminescence (such as rare earth oxides) bands and other optical properties.

5.4 Engineered Glass for Specific Optical Properties

An important distinction was made in the eighteenth century between the soda-lime *crown* and the lead-bearing *flint* glasses (Chapter 10.10). Although hundreds of new compositions have been designed since the beginning of the twentieth century, this distinction remains useful to characterize the refractivity and dispersion of optical glasses, which can now be varied over large domains (Figure 5). Systematic measurements of the index of refraction made for binary metal-oxide silica systems have been especially useful in this respect (Figure 9). Replacement of SiO_2 or network-forming Al_2O_3 by heavier metal oxides, for instance, results in a higher refractivity because the polarizability is higher for nonbridging than for bridging oxygens. But that structural factors play a significant role is actually indicated by some unexpected differences or similarities. For instance, sodium and potassium silicates have the same indices, which are lower than those of lithium silicates because of structural collapse around the small Li^+ ions. As expected, in contrast, indices are higher in alkaline earth than in alkali systems, and still more so for lead silicates. From a practical standpoint, a more important feature is the almost linear

Figure 9 Effect of composition on room-temperature refractive indices at 589 nm in binary metal-oxide silicate glasses. Source: Input data from [6].

variations of n_d with composition (Figure 9). These simple trends have been the basis of empirical models of prediction of the refractive index as a function of chemical composition, which are thus extensively used as starting points in the design of new compositions.

A simple approach is based on Lorentz–Lorenz relationship between the polarizability and refractive index, which had long proven successful when applied to organic compounds. For inorganic glasses, the molar refractivity is then related to the molar volume V_m and the index of refraction at the wavelength considered by:

$$R_m = V_m (n^2 - 1) / (n^2 + 2). \quad (7)$$

And the molar refractivity of the glass is then assumed to be the sum of the ionic refractivities of its constituting oxides:

$$R_{mi} = \sum x_i R_{mi}, \quad (8)$$

where x_i is the mol fraction of oxide i and R_{mi} , for instance, varies (in cm^3) from 0.05 (B^{3+}) and 0.07 (P^{5+}) to 0.1 (Si^{4+}), 0.17 (Al^{3+}), 0.2 (Li^+), 1.33 (Ca^{2+}), 3.1 (Pb^{2+}), and 4.3 (Ba^{2+}) [10]. But a limitation of the constant values of this model is that, in turn, the molar refractivity of oxygen (O^{2-}) cannot be considered constant as it must, for instance, varies from 3.55 (in quartz) to 4.53 (in Ca_2SiO_4) or 4.97 (in Ba_2SiO_4) to agree with the experimental data [10]. More complex models of prediction of the refractive index have thus been devised (e.g. [11]), which are beyond the scope of this chapter.

Although optical glasses were traditionally transparent only in the visible, transmission in both the ultraviolet and infrared is needed for many applications (Chapter 6.5). A higher electronic bandgap is needed to increase transparency in the UV, which one achieves easily by introducing strong ionic bonds to lower the covalent character of the glass. With about 50% covalent bonding, silica itself is quite UV transmitting but its aforementioned processing difficulties offset the advantage of not needing addition of weakly bonded modifier cations. As done with chalcogenides and fluoride glasses (Chapter 6.5), the strategy for increasing the transparency in the infrared consists in decreasing the polarity of the bonds, making the bonded species heavier and weakening bonds such that the fundamental vibrational absorption edge shifts to lower energies and, therefore, to longer wavelengths.

Many optical components require a high index to reduce the volume and, thus, the weight of the glass required. Since the refractive index is raised by a higher electron density along the light ray, it would seem logical to add to the composition heavier elements with many electrons such as lead. Whereas lead was earlier used to raise the refractive index, it also makes the glass more dispersive (Chapter 10.10). In prisms, for example, this feature was an advantage but the increased optical aberration is problematic in lenses (Chapter 10.10). Other dopants such as barium and some lanthanides are thus better suited to raise the refractive index, thanks to their high electron density, because they do not significantly raise the dispersion at the same time (Chapter 10.11). The effect is probably due to the higher ionic character of the bonding of these ions with oxygen, which increases the absorption bandgap and, thus, shifts the dispersion tail to shorter wavelengths. Although it is not itself a glass former and cannot be incorporated at contents higher than 40%, La_2O_3 has proven especially effective to raise n_d up to nearly 1.73 while keeping an Abbe number lower than 1.55 [12].

6 Interaction of Optical Components with Light

6.1 Lenses

For a thin lens whose constant radii of curvature are R_1 and R_2 , the focal length (f) in air is given by the relation

$$1/f = (n - 1) (1/R_1 - 1/R_2). \quad (9)$$

In addition to the refractive index, two other factors are at play to change the propagation of light, namely the angle of incidence angle and the optical path length of the glass. Curved surfaces, for instance, mean that the

Figure 10 Refraction of a light beam coming from the left and traveling parallel to the principal axis of lenses: convergence for a convex lens, and divergence for a concave lens. Chromatic aberration resulting from focal lengths increasing with increasing wavelength from blue to red. Spherical aberration avoided if the radius of curvature of is not constant but vary such that the lens has the shape of a rotational hyperboloid.

rays from a parallel beam of light enter the glass at different angles, therefore getting refracted at different angles both in and out of the glass as illustrated by the simple convergent and divergent lenses (Figure 10). As already understood in the Middle Ages (Chapter 10.10), thanks to these two refractions, a lens constitutes a means of focusing and defocusing the rays, thus magnifying or reducing an image or changing the light to or from a parallel beam. In all cases, further control of the effects can be made through adjustments of the refractive index and/or the physical thickness profile (the two surfaces) of the glass. Originally, the lenses used for early optical experiments were made from *crown* or *flint* glasses which were polished and ground to acquire a shape that would allow the rays of the light to be redirected as needed in the particular application. More modern optical glasses use barium as a compositional additive to raise the refractive index as it reduces the hazards associated with manufacturing components. In principle, with more modern techniques for fabrication such as chemical vapor deposition (cf. Chapter 6.4), it is even possible to produce a

functional gradient in the refractive index of a parallelepipedic piece of glass to achieve the same lens effects.

6.2 Mirrors

Like analogous lenses, a convergent mirror focuses the light whereas a divergent mirror spreads it. The fraction of light reflected is given by the reflectivity (R), which depends on the indices of refraction of the two media involved, on the angle of incidence, and on light polarization. For normal incidence, polarization is not relevant and the reflectivity reduces to

$$R = |(n_1 - n_2)/(n_1 + n_2)|^2. \quad (10)$$

For a crown glass ($n = 1.5$) in air, the reflectivity thus is 4%.

As reflective optical components, mirrors are made by application of a thin layer of metal to a pristine glass surface. Many mirrors for optical experiments and instrumentation require the metallic film to be deposited on a shaped substrate such as spherical, or even parabolic, again to allow control over the direction of the light rays. Glass was typically used because it is easy to mold and subsequently machine/polish to a desired shape. For a low precision (e.g. decorative) mirror, the metal can be applied to the rear of the glass so as to be protected from mechanical damage. But the accuracy of the image reflected by the metal layer can be impacted by the optical transmission within the glass plate. For high-precision optics, therefore, the metal is applied to the atomically flat front surface of the glass. The glass substrate for the metallic surface can be molded, machined, and polished to be anything from plane to spherical or parabolic surface depending on the intended function of the mirror. The metal used for optics in the visible region was originally a tin/mercury amalgam before the much less hazardous silver could be deposited in the nineteenth century. Today, a good reflectivity is achieved with either silver or aluminum to which a little copper is added. With modern techniques, a large variety of coatings are in fact commonly deposited in several layers to ensure good bonding and protection against oxidation (Chapter 8). For infrared light, gold may be used as the reflective metal.

6.3 Filters

Filtering out a single or a range of wavelengths to ensure that only specific frequencies are allowed to pass usually requires the band structure of the glass to have dopant quantities of colorant species (Chapter 6.2). Many of these ions are either transition metals or rare earths. There are some limited glasses with other dopants such

as uranium or other actinides. In the early days of optical filters, transition metal ions were used because for many of them the d-block absorptions gave an intense color in the visible for only a modest dopant level. The main problem with these outer d-block orbitals is that the ions can have different oxidation states, whose energies are impacted by the surrounding anions, their number, their geometry, and their bond length. Known as the ligand-field effect, this feature is the principal reason why a particular transition metal such as chromium can produce different colors in different oxide environments (Chapter 6.2).

6.4 Prisms and Gratings

Highly refractive glasses were often used for prism to disperse white light into its individual colors. Thanks to their higher dispersion, the original flint glasses were thus preferred in these applications. In more modern experiments, diffraction gratings are often favored because they can be work both in reflection or in transmission. In a grating, slits or grooves with a spacing d wider than the wavelength of the light of interest act as individual point sources interfering with one another constructively or destructively depending on the incident angle:

$$d \sin \theta_{\max} = m\lambda. \quad (11)$$

The order m of the diffraction strongly depends on the shape of the grooves. In view of the difficulties met when machining them on the original glass substrates, however, grooves are now generally ruled on polymer substrates with holographic rather than mechanical techniques.

7 Perspectives

From optical benches in research laboratories to modern telescopes, microscopes, and cameras, inorganic glasses have no competitors for high-quality optics owing to an unmatched capability to tailor their refractive and dispersive properties in wide domains through compositional adjustments (Figure 5). The prospects for widening further these domains are weak, however, because the effects of all economically affordable elements have already been investigated. Actually, some of them like thorium, beryllium, or cadmium would be of interest but their use is ruled out for obvious environmental reasons. In parallel, the quality of the glass itself has been much improved. Some of the defects that plagued early opticians remain present, but at extremely low levels. Improvements in melting procedures and batch homogenization combined with a better understanding of relaxation processes (Chapter 3.5) makes it, for instance, possible to achieve

indices of refraction constant to within $5 \cdot 10^{-7}$ and to reduce bubbles to levels so low that their total cross sections can be only 0.006 cm^2 in a volume of 100 cm^3 [12]. At the same time, mechanical and physical properties and chemical resistance to the atmosphere, stain, acids, alkalis, or phosphates have also been optimized for the intended conditions of use.

A review of only the most important current applications of optical glasses is clearly beyond the scope of this chapter. Homogeneous glass is the basic component of the tens of lenses, mirrors, and beam splitters assembled on optical benches to propagate or condition light, in particular for a wide variety of spectroscopy experiments (Chapter 2.2) that can be made on samples as small as a few microns directly observed under extreme conditions of temperature or pressure. Likewise, the simple design of the original microscopes and telescopes has been replaced with very complex setups (e.g. [13, 14]). In a modern microscope, a single objective may, for instance, consist of a set of up to 15 lenses to correct all kinds of aberrations, reduce background noise, and yield sharp images even at large fields of view. For obvious reasons, thinner and more lightweight lenses are preferred, which implies higher refractive indices.

In the design of such instruments, computer modeling has largely taken over traditional optical-table experiments to determine the shape and type of glass needed for a particular component and to test and verify their intended combinations. But inorganic glasses can be very good at producing some unexpected results at the physical modeling stages of the making the components so that some compositional iteration may still be required at this stage.

Concerning the resources, one should note that traditional inorganic glasses requires much energy to be synthesized but also that the raw materials used are quite plentiful and relatively inexpensive. We might thus see a resurgence of inorganic glasses for traditional optical applications, especially where large volumes are required, as a way toward a greener environment.

In at least two important applications, inorganic glasses have nonetheless been replaced by organic polymers (Chapter 8.8) whose lightness, resistance to mechanical shock, and easy forming have been major assets. These are eyeglasses and lenses for cell phones, tablet computers, or personal assistants with market sizes of the order of billions of units in each instance. The quality achieved in the latter case by lenses with a focal length of 4.5 mm yielding a resolution ranging from 0.3 to 12 MP is a real technological feat, especially when one considers that these lenses are produced by injection molding at a very low price – from 3 to 5 US\$ in the early 2010s – and that a mechanical zoom is not common for cost and size

reasons [7]. As impressive as they are, polymers nonetheless suffer from intrinsic limitations. These are clearly revealed by a comparison of their Abbe diagram with that of oxide glasses (Figure 5), which points to a rather narrow range of refractive indices so that inorganic glass thus remains without rival for high-precision optics. As for their lesser sensitivity to temperature and the improvements currently made in terms of scratch resistance, they are important practical advantages that give them another edge over polymers.

The Color of Glass

Georges Calas, Laurence Galois, and Laurent Cormier

Institut de Minéralogie, de Physique des Matériaux et de Cosmochimie, Sorbonne Université - CNRS - IRD - MNHN, Paris, France

1 Introduction

Color has been a most attractive feature of glass for millennia, from the glazes and pearls of the Suse period (4000 BCE) to the elaborated Roman houseware at the beginning of our era and to the stained glasses that blossomed during the European Middle-Ages. The kaleidoscope represented by medieval stained glasses (Figures VI and 1) illustrates the wide range of coloration of these glasses. The analysis of the coloration mechanisms gives information on the elaboration conditions, redox, and fining conditions.

The control of color throughout the synthesis process is a key component of glassmaking. This importance was underlined by Weyl's founding book, "*Colored glasses*," where much of the knowledge on this topic available in the 1950s was summarized [1]. In present-day technology, functional glasses are often developed because absorption bands within UV and IR regions give rise to specific applications. This is, for instance, the case of iron-bearing glasses for which the main absorption band of Fe^{2+} in the 1000–1200 nm region makes efficient absorption of solar energy possible, while keeping light transmission in the visible range sufficient to ensure adequate visibility through car windshields. On a more general basis, the limited energy range in which oxide glasses are absorbing, because of the presence of (un)wanted impurities, does not preclude these glasses to be commonly transparent in the near-IR (Chapter 6.1), which is an important parameter for modeling the diffusive radiative transport.

The color of a glass depends on light absorption, scattering, or reflection at wavelengths in the

immediate vicinity of the visible spectral region. As other coloration processes, it depends also on the incident light source used and on the observer's eye sensitivity. In the absence of coloring agents such as chemical impurities, defects, clusters, and nanophases, most oxide glasses are colorless because they do not absorb visible light. This is the very reason for their extensive use as components for optical instruments or communications, e.g. silica glass for light transmission down to 160 nm, beyond the transmission domain of the Earth's atmosphere.

In the presence of impurities or structural defects, glasses are colored by selective absorption in specific regions of the visible spectrum. Optical absorption then gives indications on the nature and structural environment of coloring species and, in turn, on glassmaking parameters such as batch composition, furnace atmosphere, melting temperature, or duration of the melting process. Glass color is an exemplary illustration of structure–property relationships in glasses [2] through the connection between the atomic-scale structure of the glass and the nature and the intensity of the absorption bands that cause glass coloration. As will now be shown, the physical mechanisms behind coloration can be ligand-field effects, charge-transfer processes, or quantum-confinement effects in metal or semiconductor nanoparticles.

2 Background on Color Processes

2.1 Light Transmission by Glasses

The color of glass arises from variations in the light transmission efficiency throughout the visible spectrum, which lies between about 400 and 800 nm (Chapter 6.1). At the origin of coloration are absorption bands or

Reviewers: P. Bingham, Sheffield Hallam University, Sheffield, UK

absorption edges whose effects are measured in terms of light transmission T through a glass plate

$$T = I/I_0, \quad (1)$$

Figure 1 French stained glass from the thirteenth century (cf. Figure VI). (a) Notre-Dame of Chartres cathedral (1215–1240), Bay 5, James and Josuas, detail of The life of St. James the Greater (cf. Figure VI), Chartres. © Malnoury, Robert; Martin, J., Inventaire général, ADAGP. (b) Sainte Chapelle, Paris (1245–1250). © RMN (Musée de Cluny, Paris). (See electronic version for color figures)

where I_0 and I represent the intensities of the incident and transmitted light, respectively. Reflection losses occur at glass–air interfaces, however, but they are readily accounted for because the intensity of the incident (I_{in}) and reflected ($I_{\text{Reflected}}$) beams are related by

$$I_{\text{Reflected}} = I_{\text{in}} (n - 1)^2 / (n + 1)^2, \quad (2)$$

where n is the index of refraction of the glass. For a soda-lime-silica glass ($n = 1.523$), Eq. (2) indicates that a fraction f of approximately 0.04 of the incident beam is reflected at each interface, regardless of the wavelength in the visible region where n varies by about 0.01.

Because light absorption depends on both glass thickness (l) and concentration of coloring elements (c), a more fruitful assessment of the process relies on Beer–Lambert law, which relates for a given wavenumber the absorbance A to these parameters and to the molar absorption coefficient ϵ (also known as molar extinction coefficient, or molar absorptivity)

$$A = \log (I_0/I) = \log (1/T) = \epsilon cl. \quad (3)$$

The ratio A/l is referred to as the linear absorbance, allowing comparison between samples with different thicknesses. As indicated by Eq. (3), the transmission as a function of wavelength and absorbance as a function of wavenumber are easily interconverted. For a soda-lime glass, however, the two representations do not carry the same information in the visible and near-infrared spectral regions (Figure 2). Whereas transmission is the property of interest in practical applications, the absorption spectrum has to be considered instead in order to understand the coloration mechanisms because its bands can be assigned to definite structural components. Transmission to absorbance interconversion is probably one among the most spectacular structure–property relationships in materials.

At short wavelengths (or high wavenumbers), one observes the onset of UV absorption, which is due to electronic transitions between the valence and conduction band tails across the bandgap. This absorption edge can be described by another absorption coefficient, α , which follows an exponential Urbach-type law as a function of the wavenumber ν ,

$$\alpha \sim \exp (h\nu/E_u), \quad (4)$$

where E_u is the Urbach energy that accounts for the energy distribution of the localized states in the valence band tail. On this absorption edge are superimposed intense charge-transfer bands, also located in the near UV, which have a Gaussian lineshape (see Section 5).

Figure 2 Glass coloration as examined from the standpoints of absorption and transmission for a soda-lime silicate glass containing 0.87 wt % Fe_2O_3 (sample thickness 4 mm). In the absorbance spectrum (a), the electronic transitions of Fe^{2+} and Fe^{3+} are clearly apparent in the near IR and visible-near UV, respectively. As to the transmission spectrum (b), it is used to represent coloration and provides colorimetric parameters. *Source:* After [3]. (See electronic version for color figures)

2.2 The Role of Transition Elements as Coloring Agents

The color of glass is generally due to electronic transitions in transition elements between localized electronic energy levels that are split by the ligand field. Transition elements are characterized by the presence of unpaired electrons in partially filled d- or f-orbitals. Electronic transitions within these orbitals are at the origin of selective light absorption at characteristic energies, usually within or in the vicinity of the visible spectrum [4]. The energy and intensity of these transitions vary as a function of the transition metal ion present, its oxidation state, and its immediate surrounding (site symmetry, nature of the ligands).

As d–d transitions are parity forbidden according to the selection rules for electric dipole transitions (Laporte

rule), transition elements in principle should not have a high coloring efficiency. This feature holds particularly true for 4f-elements, in which the electronic levels retain an atomic character because 4f-orbitals are shielded by the outer electronic shells and not admixed with other electronic states. Hence, the molar absorption coefficient of lanthanides is 5–10 times smaller than that of 3d elements, yielding only faint colors even at concentration levels of several wt %.

For d-transition elements, the d-orbitals are not shielded by outer orbitals so that there is some admixture with other states when there is no inversion center at the site occupied by the transition element (distorted sites, tetrahedral or 5-coordinated sites). This admixing partially relaxes the Laporte selection rules, making 3d-elements such as Fe, Cu, Cr, V, Mn, Co, and Ni the major

coloring agents in glasses. Two main mechanisms are involved: (i) electronic transitions between crystal-field split 3d-electronic levels; (ii) charge-transfer processes, i.e. a transfer of the electronic density between the transition element ion and its ligands or other neighboring transition elements. As compared with the former, the latter is allowed and then results in an intense coloration. In both cases, optical transitions depend on the speciation of the transition element, namely its oxidation state, coordination number, site distortion, and on the nature of the chemical bond with its ligands (Table 1).

2.3 The Sites Occupied by Transition Elements in Glasses: A Limited Disorder

The fact that glass coloration can be assigned to one or several species of transition elements indicates the presence of well-defined cation sites. It is thus an obvious inadequacy of the Zachariasen model of oxide glasses not to describe the local environment of cations. During the last decades, many experimental studies and numerical simulations have demonstrated that the structure of oxide glasses and melts is more organized than assumed with a continuous random network. They have shown that cations are not restricted to fill holes within the polymeric network but tend to define their own environment according to the well-known crystal-chemical rules that exist in crystals. A major advance has thus been this conclusion that cations have a heterogeneous structural distribution, which contributes to an original medium-range order of oxide glasses and makes it possible to explain charge-transfer processes involving transition elements.

Because of a usually lower density caused by atomic disorder, the coordination number of cations is generally lower in glasses than in crystals of similar composition. Some cations mimic network formers by occurring in tetrahedra connected to the polymeric network within a well-defined topology: such are the cases of tetrahedral Ni^{2+} , Zn^{2+} , and Fe^{3+} . Network modifiers are cations such as alkalis or alkaline earths that are 6- or higher-coordinated. Contrary to what is observed in crystals, however, few transition metal ions are octahedrally coordinated in glasses and there is no evidence for higher coordination of 3d ions. The most important ions adopting an octahedral coordination are trivalent and highly charged cations such as Cr^{3+} , V^{3+} , or Zr^{4+} , as well as Co^{2+} and Ni^{2+} in the special case of alkali-poor borate glasses where they occur as CoO- and NiO-derived 2-D-nanodomains.

Other transition metal ions such as Fe^{2+} , Ni^{2+} , and Fe^{3+} are frequently distributed among various site geometries whose proportions and resulting effects on color depend on chemical composition. They are often 5-coordinated – a coordination seldom observed in crystals – which gives rise to original colorations. This structural evidence points to the presence of small sites where cations have a structural role intermediate between those of network formers and modifiers. But the fact that transition metal ions cause well-defined optical absorption spectra in glasses indicates that their site distribution is limited despite the amorphous structure of these materials. The need for satisfying the charge neutrality of ligands implies a connection to the glassy polymeric network and indicates that a concept of quasi-molecular complexes does not describe the actual structural location of these ions.

Figure 3 Successive splittings of d-orbitals of transition elements in different coordination numbers and site geometry. The dashed lines represent the electronic transitions that can be observed in a one-electron system.

3 Crystal-Field-Driven Glass Color

3.1 Crystal-Field Effects

The relative energy of d-orbitals varies as a function of the coordination number and distortion of the site occupied by the transition element, and by the bond covalency with the ligands. All these factors give rise to characteristic splittings (Figure 3) that make transitions between these electronic levels possible with a selective absorption of light that causes glass coloration. The position of these electronic levels gives indications on the local symmetry and magnitude of the ligand field splitting.

The intensity of these transitions is determined by selection rules for which the spin state of the transition

metal ions plays an important role since absorption bands are less intense when the transition implies a change of the electron spin. For instance, Mn^{2+} and Fe^{3+} are not efficient coloring agents because both ions have five electrons occupying the five d-orbitals (Figure 4a), which leaves room for only spin-forbidden transitions of low intensity. Although less abundant than Fe^{3+} in glasses melted in air, Fe^{2+} gives them their characteristic green coloration caused by the presence of an intense absorption band in the near-infrared because a sixth 3d-electron (Figure 4a) produces spin-allowed electronic transitions. This contrast is reflected in the molar absorption coefficient of these ions, which is an order of magnitude lower for Fe^{3+} relative to Fe^{2+} (Figure 4b). Molar extinction

Figure 4 Influence of the electronic configuration on the optical absorption efficiency of Fe^{2+} and Fe^{3+} . (a) Schematic representation of the population of 3d orbitals. For Fe^{3+} , five electrons occupy the five d-orbitals so that d–d transitions are forbidden. For Fe^{2+} , the sixth electron gives rise to an electronic transition. (b) Spectral dependence of the molar absorption coefficient of Fe^{3+} and Fe^{2+} in a soda-lime-silica glass. Source: After [3]. The large difference in coloring power between these oxidation states results from the different electronic configuration shown in (a).

coefficients are important to model optical absorption spectra in glasses, provided the chemical composition of the glasses be similar: as optical properties are additive, it is possible to compute optical absorption spectrum expected from the presence of various coloring elements (Table 2).

Finally, another factor to be taken into account is the electrostatic repulsion between 3d-electrons because it influences the optical absorption spectra by shifting the free-ion electron energy levels prior to the action of crystal field. This interelectronic repulsion can be expressed in terms of three parameters A, B, and C known as the Racah parameters (after Giulio Racah, who first described them). Racah parameters are ion-specific and for a given ion vary with the electron localization (i.e. with cation-ligand bond covalency). The reduction of interelectronic repulsion between the 3d-electrons corresponds to a more covalent character of the transition metal ion oxygen bond.

3.2 Peculiar Sites, Peculiar Colors: The Example of Ni^{2+}

Nickel yields colors ranging from brown and yellow in Na-, Li-, or Ca-bearing glasses to purple or blue in K-,

Rb-, or Cs-bearing glasses or, less commonly, green or even orange in some alkali-deficient borate and borosilicate glasses (Figure 5). This broad palette of hues in oxide glasses is directly related to the varying coordination of Ni^{2+} [6]. Probably one of the most commonly observed colors, the brown arises from continuously decreasing absorption from the purple to the red parts of the visible domain along with the absence of an absorption maximum in the visible domain. That color is indeed very sensitive to local structure as shown by a comparison between the optical absorption spectra of crystalline and glassy $\text{CaO} \cdot \text{NiO} \cdot 2\text{SiO}_2$ (Figure 6). The former has the light green color characteristic of $^{[6]}\text{Ni}^{2+}$. In the latter, Ni^{2+} occupies a small proportion of tetrahedral sites but it is mostly present in triangular bipyramids that give rise to the brown color through a broad, asymmetric absorption band around $22\,500\text{ cm}^{-1}$ (444 nm). Weak and broad absorption bands in the visible and near-infrared correspond to the other electric transitions expected for $^{[5]}\text{Ni}$. The existence of these $^{[5]}\text{Ni}$ sites has been confirmed by complementary Ni K-edge extended X-ray absorption fine structure (EXAFS) and X-ray absorption near edge structure (XANES) spectroscopy and neutron diffraction coupled with isotopic substitution. As underlined below for Fe^{2+} , however, most methods do not

Figure 5 Optical spectra and structural models explaining the color of purple, brown, and green borosilicate glasses containing Ni^{2+} in four-, five-, and sixfold coordination, respectively. Source: After [5]. (See electronic version for color figures.)

provide indication on the actual site geometry of the ^{55}Ni site, which has been mostly derived from optical absorption spectroscopy.

Optical transitions from tetrahedral Ni^{2+} are present as a minority contribution in most optical absorption spectra of Ni-bearing silicate, aluminosilicate, and borosilicate glasses, with the noticeable exception of low-alkali borate or borosilicate compositions. In glasses containing large alkalis (K, Rb, Cs), $^{44}\text{Ni}^{2+}$ causes a blue/purple coloration through the presence of an intense absorption band located near $16\,000\text{ cm}^{-1}$, in the red region of the visible spectrum, and a transmission window at short wavelengths (Figure 5). This chemical dependence of glass coloration will be discussed in Sections 4.1 and 6.1.

3.3 Peculiar Sites with a Continuous Site

Distribution: Fe^{2+} and Fe^{3+}

Although iron is the most common coloring element in glasses, the geometry of the sites occupied by Fe^{2+} and Fe^{3+} is still a matter of debate in spite of numerous studies made with a broad range of structural and spectroscopic methods that includes X-ray and neutron diffraction, Mössbauer spectroscopy, electron paramagnetic resonance, XANES and EXAFS, optical absorption, and luminescence (Tables 1 and 2).

Like for Ni^{2+} , there is no evidence for octahedral coordination of Fe^{2+} in silicate glasses, but the picture is less clear-cut for Fe^{3+} . The optical absorption spectrum

of Fe^{2+} shows two absorption bands, the most intense near 9000 cm^{-1} with an extension to higher wavenumbers in the red region that also affects glass coloration. A significant absorption down to $16\,000\text{ cm}^{-1}$, i.e. outside the absorption domain of octahedral Fe^{2+} in crystals, indicates the presence of ^{55}Fe . A detailed magnetic circular dichroism study has confirmed that the Fe^{2+} absorption band is mostly caused by four- and fivefold coordinated species [7]. This result agrees with Mössbauer and Fe K-edge XANES and EXAFS data, which indicate that Fe^{2+} coordination varies continuously from four- to

Table 1 Glass coloring mechanisms.

Cause of coloration	Examples	Efficient concentration
Crystal-field transitions	d-Elements	0.1–10 wt % ^a
Atomic-like transitions	4f-Elements	1–10 wt %
Ligand to metal charge transfer	O– Fe^{3+} , O– Ce^{4+} , S^{2-} – Fe^{3+} , O^{2-} –U(VI)	10–1000 ppm

Nanoparticles	Au^0 , AgCl, Cd(S, Se)	10–100 ppm

^a Lower efficient concentrations for $^{44}\text{Co}^{2+}$ (some 10–100 ppm) and 4d- and 5d-elements (e.g. Pt^{4+} : a few 100 ppm).

Figure 6 Effect of nickel coordination on the absorbance spectra (derived from diffuse reflectance) of $\text{CaNiSi}_2\text{O}_6$ crystal and glass which are green and brown, respectively. The position of the three similarly intense peaks of octahedral Ni^{2+} in the crystal (O) contrast with the two weak peaks and the large high-energy band produced by Ni^{2+} in the trigonal bipyramids of the glass (P), to which tetrahedral Ni^{2+} contributes a shoulder (T). Source: After [6]. (See electronic version for color figures.)

Table 2 Color yielded by various transition metal ions in glasses.

Oxidation state	Coordination number	Color
Ti^{3+}	6 (distorted)	Lilac
V^{4+} (VO^{2+})	6 (distorted)	Blue
V^{3+}	6	Green
Cr^{VI} (CrO_4^{2-})	4	Yellow
Cr^{4+}	4	Blue
Cr^{3+}	6	Green
Cr^{2+}	6 (distorted)	Blue
Mn^{3+}	6 (distorted)	Purple
Mn^{2+}	4, 5	Light yellow/orange
Fe^{3+}	4, 5	Light yellow
Fe^{2+}	4, 5 (6?)	Green
Co^{2+}	4	Violet blue
Ni^{2+}	6	Apple green, yellow
Ni^{2+}	5	Brown
Ni^{2+}	4	Blue, purple
Cu^{2+}	6 (distorted)	Blue
Pt^{4+}	6	Yellow

fivefold. These complementary techniques do not provide further information on the actual site geometry of ^{55}Fe sites, however, which may range from a square pyramid to a trigonal bipyramid geometry. Optical absorption spectra are very sensitive to this variation in the local symmetry that gives rise to distinct electronic transitions. A modification of the geometry of the ^{55}Fe site as a function of glass composition may explain the variations observed in the position of the broad Fe^{2+} absorption band near $10\,000\text{ cm}^{-1}$ in glasses. This continuous distribution thus contrasts with the bimodal distribution between discrete site geometries observed for Ni^{2+} , each one being characterized by well-defined spectroscopic parameters.

Owing to experimental difficulties, the interpretation of the Fe^{3+} optical absorption bands in glasses has also been much discussed. It nonetheless appears that (i) the most intense bands arise from field-independent transitions that do not depend on site geometry; (ii) the other crystal-field transitions are superimposed on and can be obscured by the tail of the intense O–Fe charge-transfer transitions that occur in the near UV; (iii) as underlined in Section 3.1, Fe^{3+} transitions are spin-forbidden and hence of lower intensities than those of Fe^{2+} by more than one order of magnitude. In a recent investigation of glasses in which iron was fully oxidized, however, Fe^{3+} speciation could be unambiguously determined by EXAFS [8]. Providing information on the origin of the transitions observed in the optical absorption spectra, this study clearly showed that Fe^{3+} coordination is changing from 4 to 6 as a function of the nature and concentration of the alkali and alkaline earth cations present, the coordination number of Fe^{3+} increasing with decreasing cation ionic radius ratio. Alkali–alkaline earth glasses show evidence of a stabilization of $^{44}\text{Fe}^{3+}$, illustrating a preferential link between ^{44}Fe and the alkalis [8] and indicating that transition metal ions are not probing the average glass structure, but favor some local surroundings.

3.4 Presence of One Site Geometry: Cr^{3+}

Like in most crystalline compounds, Cr^{3+} occurs in glasses only in octahedral coordination because of the high crystal-field stabilization energy of the d^3 configuration. The crystal-field spectrum of Cr^{3+} exhibits two broad, intense bands at $15\,000$ and $22\,000\text{ cm}^{-1}$, which occur in the visible range and have characteristic Gaussian line shapes with bandwidths close to that observed in crystals (Figure 7). This is consistent with the observed Cr–O interatomic distances and their small radial disorder determined by Cr K-edge EXAFS. These absorption bands define transmission windows near $10\,000$, $18\,000$, and $27\,000\text{ cm}^{-1}$: only the second one is responsible for the characteristic green color observed in Cr-bearing

Figure 7 Molar extinction coefficients of Cr^{3+} in K-, Na-, and Li-trisilicate glasses (referred to as KS3, NS3, and LS3, respectively); experimental spectra (solid curves) and fits made with Gaussian bands (dashed curves), which are also plotted as dotted curves for LS3. For clarity, the data for NS3 and KS3 have been shifted upward by 2.7 and 12 l/mol/cm, respectively. Source: After [9] (See electronic version for color figures.).

glasses since the others are outside the visible spectrum. Additional weak features near the maximum of the bands are linked to field-independent spin-forbidden transitions, resulting in characteristic interference dips.

Other transition-element cations exhibiting only one site geometry in glasses include Ti^{3+} , V^{3+} and V(IV) (actually the vanadyl group, VO^{2+}), Cr^{2+} and Cr^{4+} , etc. Special mention must be made of Mn^{3+} and Cu^{2+} for which the main absorptions band undergo Jahn–Teller splitting of the excited e_g level through spontaneous distortion of the octahedral coordination, which increases the crystal-field stabilization energy. As a result, Mn^{3+} allows light transmission in the red and violet part of the visible spectrum, resulting in the characteristic pink/magenta color of Mn-bearing glasses, whereas Cu^{2+} exhibits a unique, large transmission window in the blue-green part of the spectrum.

3.5 The Case of Silent Species: Co^{2+} -Bearing Glasses

The typical blue color of Co-bearing glasses is due to an intense absorption band located in the orange and red parts of the visible spectrum that is characteristic of $^{44}\text{Co}^{2+}$ (Figure 8). This assignment from optical absorption spectroscopy is in agreement with XANES and EXAFS data. Even though the hue of Co-bearing glasses

Figure 8 Influence of the nature of the alkali cation on the intensity but not on the lineshape of the optical absorption bands of Co^{2+} -bearing $\text{K}_2\text{O}\cdot\text{CaO}\cdot 4\text{SiO}_2$ (blue) and $\text{Na}_2\text{O}\cdot\text{CaO}\cdot 4\text{SiO}_2$ (red) glasses. Absorbance is represented as represented by the molar extinction coefficients, allowing quantitative comparison between the two glasses. Source: After [10]. (See electronic version for color figures.)

does not vary much with glass composition, the intensity of the coloration (and hence of the absorption bands) does change. As an example, replacement of K by Na in $\text{R}_2\text{O}\cdot\text{CaO}\cdot 4\text{SiO}_2$ ($\text{R} = \text{K}, \text{Na}$) glasses decreases the optical transition intensity by 35% whereas the molar extension coefficient of $^{[4]}\text{Co}^{2+}$ complexes is only half of the values reported for potassium and sodium silicate glasses. This is an indication that Co^{2+} converts to less absorbing, *silent* species when replacing a given alkali by either a smaller alkali or alkaline earths. As indicated by EXAFS data, the smaller molar extension coefficient cannot be attributed to a distortion of the Co tetrahedral site, as observed in crystals. These observations suggest the presence of higher coordinated, weakly absorbing species, that are difficult to quantify because the optical absorption bands of $^{[4]}\text{Co}^{2+}$ overlap the transitions expected for $^{[5]}\text{Co}^{2+}$ and $^{[6]}\text{Co}^{2+}$. Although the low intensity of these spectroscopically silent species does not help in recognizing them in optical absorption spectra, they directly affect the intensity of light absorption and hence the efficiency of Co^{2+} as a coloring agent.

4 Variation of Glass Coloration

4.1 Dependence of Color on Glass Composition

Changing glass composition affects the effective charge of the oxygen ligands, and hence crystal-field splitting magnitude as well as cation-oxygen covalence. Transition elements are indeed interesting structural probes of glass

Figure 9 Variation of Cr^{3+} crystal-field splitting, represented as the crystal field stabilization energy (CFSE), as a function of optical basicity in glasses. Filled squares: multicomponent silicate and aluminosilicate glasses, which mimic chemical variations during magmatic differentiation; open circles: alkali silicate glasses (NS, KS, and LS refer to sodic, potassic, and lithic silicate glasses, respectively, NBS and KBS stand for sodium and potassium borosilicate glasses) and Di for diopside ($\text{CaMgSi}_2\text{O}_6$) glass; filled triangles: alkali borate glasses. Source: After [11].

structure. Two different cases can be distinguished in this respect. When only one site geometry exists (e.g. Ti^{3+} , Mn^{3+} , Cr^{3+} , V^{4+} , and V^{3+}), the chemical dependence of the optical spectra manifests itself mostly through a shift of the main absorption bands. When two sites (e.g. Ni^{2+} , Ti^{4+}) or more (e.g. $^{[4]}\text{Fe}^{2+}$ and $^{[5]}\text{Fe}^{2+}$, $^{[8]}\text{Nd}^{3+}$ and $^{[9]}\text{Nd}^{3+}$) are present, their relative proportions vary with glass composition without much shifting of the electronic transitions. An abundant bibliography exists in this domain, but is mostly restricted to some specific glass systems. We will illustrate this section with Cr^{3+} and Ni^{2+} .

4.2 Variation of Site Geometry: Presence of a Single Type of Site

The case of Cr^{3+} has been studied extensively. This cation retains a regular octahedral coordination in most oxide glasses [11] in spite of some variations in the magnitude of crystal-field splitting and of disorder effects induced by glass composition mostly as a function of the nature of the modifier cation (but not of its concentration). In multicomponent glasses (Figure 9), the crystal-field intensity increases with optical basicity (cf. Chapter 5.7). In alkali silicate glasses, however, it varies only with the nature of the alkali and not with its concentration. In mixed

alkali-alkaline earth glasses, optical absorption parameters in addition remain close to the values found in binary silicate glasses with the same type of alkalis, which reveals that Cr^{3+} shows a strong preference for alkalis in its immediate environment. These observations indicate that Cr^{3+} is insensitive to the overall glass structure. It builds instead its own environment, which is also demonstrated by its heterogeneous distribution in the glass structure [11].

4.3 Variation of Site Geometry: Presence of Two Sites

When a glass bears an ion such as nickel that distributes between two sites, its color varies with glass composition [6] as the fractions of $^{[5]}\text{Ni}^{2+}$ and $^{[4]}\text{Ni}^{2+}$ sites. In silicate glasses, alkalis and alkaline earths are either network modifiers when they coexist with $^{[5]}\text{Ni}$ or charge-compensators for $^{[4]}\text{Ni}$. The mean Ni speciation thus depends only on the nature of the alkali or alkaline earth. As observed in Section 4.2 for 3d-ions in a single type of site, however, the concentration of the alkali or alkaline earth does not influence glass color in silicate glasses. By contrast, in borate and borosilicate glasses, the Ni-site geometry and color progressively change with increasing alkali or alkaline earth content from octahedral (green) to distorted octahedral (yellow), trigonal bipyramid (brown), and finally tetrahedral (purple). This trend likely arises from the interaction of alkali and alkaline earths with boron when its coordination changes from $^{[3]}\text{B}$ to $^{[4]}\text{B}$ with increasing alkali/alkaline earth concentration. As a consequence, some borosilicate glasses show a peculiar orange color that is otherwise rarely encountered. In this case, Ni has the three coordination numbers 6, 5, and 4: $^{[6]}\text{Ni}$ is probably associated with the borate sublattice, and $^{[5]}\text{Ni}$ and $^{[4]}\text{Ni}$ with the silicate sublattice.

4.4 Redox Equilibria and Glass Coloration

The influence of the redox state on glass color has been much investigated [12]. For instance, Cr-bearing glasses show a change in glass color from green to yellow when melting conditions vary from reducing to oxidizing. This trend is due to the formation of a chromate complex $(\text{CrO}_4)^{2-}$ that gives rise to a charge-transfer transition from oxygen to chromium located near $28\,000\text{ cm}^{-1}$ in oxidized glasses (Figure 10). The tail of this intense band extends from the UV to the visible and is superimposed on the Cr^{3+} absorption bands because there exists a considerable difference between the molar extinction coefficients of Cr^{3+} and Cr^{6+} , which are 18–20 and $4200\text{ l}/(\text{cm}/\text{mol})$, respectively. As a result, optical spectroscopy measurements of the chromium redox state cannot be made

Figure 10 Linear absorbance spectra of Cr^{3+} and $(\text{CrO}_4)^{2-}$ in soda-lime-silica (SCN) and sodium borosilicate (SBN and SBNox) glasses. The position of the absorption bands characteristic of the two oxidation states of chromium in the glasses is indicated. *Source:* After [14].

on glasses in the presence of relatively high concentrations of Cr^{6+} in the form of chromate groups. Wet chemical analysis or other spectroscopic methods have to be performed instead.

The interaction between redox pairs is widely used during glass fining. For instance, manganese has traditionally been known as the *glassmaker's soap* because, if added to soda-lime-silica glass in the form of an oxide such as MnO_2 , it makes the green color arising from iron impurities less intense by oxidizing Fe^{2+} into Fe^{3+}

And because only spin-forbidden transitions are associated with the d^5 configuration of both Mn^{2+} and Fe^{3+} (Figure 4a), their low intensities result in weakly colored glasses. The effect is not permanent, however, as the interaction with sunlight (solarization) favors the reverse reactions:

As illustrated by old windows and doorknobs, this phenomenon is at the origin of the well-known *purple glass* of which *desert amethyst glass* is a natural variety.

5 Temperature Dependence of the Optical Absorption Spectra of Glasses: Thermochromism

Color changes are often spectacular upon heating: brown Ni-bearing glasses, for instance, turn blue or green Cr³⁺-bearing glasses into yellow (Figure 11). Like for the chemical dependence of glass coloration, there is a marked difference between transition elements depending on whether they occupy one or several sites. In the latter situation, temperature modifies the equilibrium between the site populations whereas in the former, the site of the coloring element expands with increasing temperature. Because of the difficulty of recording high-temperature optical absorption spectra, however, data are scarce so that we will restrict ourselves to discussing investigations made below T_g . We nonetheless warn that important modifications of the optical spectra may take place in the molten state.

5.1 Coexistence of Well-Defined Sites: Ni²⁺

In a classic piece of work, Lin and Angell [15] investigated the optical absorption spectra of Ni²⁺ in a potassium triborate glass and melt to 1000 °C. In the starting glass, Ni²⁺ is distributed between 4- and 5-coordination as in most oxide glasses (see Section 3.1). Major changes occur in the vicinity of T_g , above which the proportion of ^[4]Ni²⁺ increases. This is likely related to

Figure 11 Green Cr-containing glasses turning yellow at ca. 500 °C, a direct illustration of the thermal expansion of cation sites in glasses. (See electronic version for color figures)

the temperature-induced coordination changes of boron, as shown by the reaction

where Na_{CC} and Na_{NM} stand for charge-compensating and network-modifying Na, respectively, and O_{NBO} for non-bridging oxygen. The ^[4]B to ^[3]B conversion between glass and melt increases alkali activity and then provides further charge compensation for ^[4]Ni, inducing the coordination change of Ni. In the borate composition investigated, the ^[4]Ni/^[5]Ni ratio is not frozen in at T_g , as these two states are separated by unusually small energy barriers. The presence of further changes down to room temperature is a direct evidence of ionic mobility while the polymeric network is frozen in. The modification of Ni- and Co-speciation in glasses at high temperature may be retained after fast quenching. This has been recently shown in Co- and Ni-bearing alkali borosilicate glasses in which the 4-coordinated species, favored at high temperature, are partly retained at room temperature by a fast quenching, illustrating the importance of thermal history on glass structure [16].

5.2 Presence of One Site: Direct Evidence of a Thermal Expansion of Cation Sites

The crystal-field strength is a sensitive probe of the environment of transition elements in crystalline compounds and of its changes under high temperatures or pressures. High-temperature optical spectra of Cr³⁺ in glasses show a systematic linear redshift of the crystal-field transition from 300 to 800 K, with an isobestic point near 17 000 cm⁻¹ (Figure 12). The transmission window similarly

Figure 12 Modification of the optical absorption spectrum of Cr³⁺ in a potassium borosilicate glass from 300 to 726 K. Source: After [12]. (See electronic version for color figures)

shifts toward lower wavenumbers, giving glasses thermochromic properties [11]. Using a point charge model, one may derive the temperature-induced variation of the Cr–O distances from crystal-field splitting, Dq

$$10Dq = \frac{5q\langle r^4 \rangle}{\bar{R}^5} \quad (6)$$

where q is the effective charge in the ligands, r the d-electron-core distance, and $\bar{R}$ the mean Cr–O distance. In this way, one estimates the linear thermal expansion coefficients of Cr³⁺–O bonds in glasses to be about $16\text{--}20 \cdot 10^{-6} \text{ K}^{-1}$. These values are independent on glass composition, contrary to what is observed for bulk thermal expansion, and they are in addition generally larger than the macroscopic thermal expansion coefficients. This lack of sensitivity of Cr³⁺ to the average glass structure is an additional confirmation of the heterogeneous structure of silicate glasses at the atomic scale [11]: Cr³⁺ does not explore an average glass structure but rather adjusts its own environment.

6 Charge-Transfer Processes: From Amber Glasses to Lunar Glasses

6.1 Ligand to Metal Charge Transfer (LMCT)

Charge transfer (CT) represents a shift of the electron charge density from one ion to a neighboring one. The most frequent processes involve transition metal ions such as Fe²⁺, Fe³⁺, Ti⁴⁺, Ce³⁺, Ce⁴⁺, and their ligands (O, S, Se...) in relation with the covalency of the chemical bond. They give rise to intense absorption bands at short wavelengths, providing a strong UV absorption in glasses that would otherwise be mostly transparent in the visible range. These glasses are thus used for solar protection and they also ensure efficient UV absorption in food containers.

The reduction of glass transparency in the UV arises from the presence of Gaussian-shaped absorption bands, superimposed on an exponential Urbach absorption edge and related to the presence of ligand-to-metal CT transitions. The intensity of these bands is larger by about three orders of magnitude than that of crystal-field transitions. The O^{2–}–Fe³⁺ CT band near $45\,000 \text{ cm}^{-1}$ dominates the shape of the UV absorption edge [17], and may be detected at low concentration down to ppm levels. For Fe²⁺, CT is about three times less intense and occurs at slightly higher energy than for Fe³⁺. Likewise, Ce³⁺ and Ce⁴⁺ are strong UV absorbers in glasses where, as observed for iron, absorption is more efficient (by a factor of 16) and takes place at higher wavenumbers for the oxidized than for the reduced form [18]. Other transition

metal ions show intense ligand-to-metal transitions in the UV, e.g. near $33\,000 \text{ cm}^{-1}$ for Ti⁴⁺ [19].

Increasing the covalency of Fe–ligand bond shifts the energy of the charge-transfer transition toward lower values. Such is the case of the well-known amber chromophore, which is widely used to efficiently absorb UV radiation and then protect radiation-sensitive liquids in glass containers (pharmaceuticals and beverages). This chromophore shows optical transition near $23\,500 \text{ cm}^{-1}$ with a molar extinction coefficient of about 9000 L/mol/cm (as compared to 25 L/mol/cm for the Fe²⁺ absorption band near 1000 nm). As a consequence, the amber chromophore contributes to glass coloration at concentrations as low as a few ppm: the high intensity of these bands causes them to extend into the visible spectrum. The continuously decreasing absorption from the violet to red gives rise to this characteristic brown coloration. The structure of this amber chromophore is still poorly known, involving ^[4]Fe³⁺ ions surrounded by one S^{2–} and three O^{2–} ions. Its stability field is then limited by two opposite redox reactions, i.e. the reduction of ferric iron and the oxidation of sulfide ligands.

A peculiar case concerns oxyanion and oxycation complexes such as chromate (CrO₄)^{2–}, vanadate (VO₄)^{3–}, or uranyl (UO₂)²⁺ groups. Under oxidizing conditions, these complexes are similar in glasses to those observed in crystals and aqueous solutions, retaining similar spectral properties. As a d⁰ system, the formal Cr(VI) or V(V) oxidation states do not have d electrons, so that the only electronic transitions occur via charge-transfer processes from ligands to the central ion, which is at the origin of the intense coloration arising from these extreme oxidation states. For instance, CT in chromate groups consists of a transfer of an oxygen p electron, constituting one of the ligand bonds of t₁π symmetry, to the central ion d-shell. Further splitting by crystal field gives rise to two absorption bands near $37\,000$ and $27\,000 \text{ cm}^{-1}$ [20]. Only the latter is usually observed because the former is hidden by the absorption of the matrix (Figure 12).

6.2 Intervalence Charge Transfer

Another type of CT involves cations with different oxidation states, which also relies on an extended covalency of chemical bonds and give rise to absorption bands so intense that these may even result in efficient coloration at concentrations down to the ppm level. Increasing the iron content in oxide glasses, for instance, increases absorption in the visible region between ligand-to-metal CT in the near UV and crystal-field transitions in the near IR so that high-Fe glasses melted in air are black (Figure 13). Evidence has been found for a contribution near $14\,500 \text{ cm}^{-1}$, assigned to Fe²⁺–O^{2–}–Fe³⁺ intervalence charge transfer (IVCT), Fe²⁺ and Fe³⁺ playing the

Figure 13 Coloration arising from charge transfer processes. (a) Dark color of $\text{NaFeSi}_2\text{O}_6$ glass (Fe^{2+} – Fe^{3+} intervalence charge transfer). (b) Orange glass (“soil”) collected during the Apollo 17 mission. Clear orange beads owe their color to Fe^{2+} – Ti^{4+} intervalence charge transfer. The black color of some grains comes from the surface nucleation of olivine crystals with intergrown ilmenite (FeTiO_3) crystals. Source: © Kurt Hollocher, Geology Dept, Union College, NY. (See electronic version for color figures)

role of electron donor and acceptor, respectively [21]. The deep-brown to black color of these glasses is an interesting visual proof for clustering of transition element in glasses with a significant covalent bonding in and between the Fe sites.

During lunar exploration, an original 3.48-billion-year-old orange glass has been found near a small crater at the Apollo 17 landing site (Figure 13). This glass color comes from a Fe^{2+} (donor)– O^{2-} – Ti^{4+} (acceptor) charge-transfer transition near $24\,000\text{ cm}^{-1}$. Synthetic glasses containing Fe or Ti and synthesized under simulated reducing lunar conditions exhibit a green or a purple color, respectively. It is only the association between the two transition elements that results in this original color [19]. This fact provides further proof of the heterogeneous distribution of transition element cations in glass structure, favoring a location in specific enriched regions. Similar Fe–Ti IVCT may be used for enhancing UV absorption in container glasses for drugs and cosmetics.

7 Absorption by Organized Clusters and Nanophases

7.1 Presence of Organized Clusters: Low-Alkali Borate and Borosilicate Glasses

Nickel- and cobalt-bearing alkali-poor borate glasses exhibit original green and light pinkish purple colorations, respectively. Similar colors are found in borosilicate

[6] but not in silicate glasses. For decades, these features have been assigned to the presence of Ni and Co in octahedral sites within the glass structure. More recently, Ni- and Co–K edge EXAFS data on these glasses have revealed cation–cation correlations up to 6 Å in ordered NiO- or CoO-based clusters and characterized by three colinear, edge-sharing octahedra, which induce a specific multiple scattering feature around 6 Å . Some structural features characteristic of the bulk oxides (CoO or NiO) are missing, however, showing that these ordered domains do not correspond to pure oxide crystallites [2]. This environment is not affected by Ni or Co concentration and disappears with increasing alkali content.

The presence of similarly ordered domains in low-alkali borosilicate glasses shows that ^{61}Ni (and probably ^{61}Co) is preferentially associated with a borate rather than with a silicate sublattice. This local coordination is likely favored by the geometrical constraints induced by the presence of rigid large ^{11}B -based superunits. But the EXAFS data indicate a less extended structural order in the NiO nanodomains, probably due to the mutual interaction between borate and silicate sublattices, which limits their extent [6].

7.2 Metallic Nanoparticles

Although *Ruby* glasses have been known for centuries (e.g. the famous fourth-century Lycurgus cup), their deep ruby-red or yellow colors have been explained only

recently in terms of precipitation of Au, Cu, or Ag nanoparticles 5–100 nm in diameter [22]. These nanoparticles form during thermal treatments above the annealing temperature of colorless starting glasses prepared under reducing conditions such that the dilute (40–300 ppm) coloring metal ion is present in its reduced form (e.g. Au^+). Gold reduction has been accomplished historically by using Sn as a reducing agent, following the reaction:

However, the electrons needed for gold reduction may be provided by other redox reactions and even from external irradiation. The ruby-red color of the gold nanoparticles is due to a resonant absorption of photons during the excitation of surface plasmons within the nanoparticles. It is a typical example of quantum (electron) confinement effects observed when crystallites are smaller than the wavefunction of an electronic state. This color is often referred to as *striking* because it suddenly appears upon heating.

7.3 Photochromic Glasses

Photochromic glasses darken or change color when exposed to light or UV radiation, giving rise to a wide range of applications such as ophthalmic lenses, architectural or automotive glazing, information storage, and display devices [23]. A phenomenon that has found important practical applications in optics relies on the presence of silver halide particles of a few nm precipitated in the glass through an appropriate heat treatment. When the glass is exposed to near-UV visible light, a dark coloration rapidly appears but the glass lightens more slowly when returned to the dark. It is interesting that generally the glasses do not darken completely inside a car, because the car windows block some of the UV radiation needed for the photochromic reaction. Temperature effects are intriguing: the higher the temperature, the less dark photochromic glasses will be, as, conversely, photochromic glasses will take longer to regain their transparency under low ambient temperature.

Under exposure to light, Ag^+ is reduced into Ag^0 , the halogen ions acting as the reducing agent providing electrons for silver particle formation. This results in light absorption by the conduction electrons of metallic Ag over the entire visible range, giving a neutral coloration (Figure 14). Some sensitizers such as Cu^+ may be added to speed up the process, which act as an electron donor for Ag^+ . The limited diffusion of halogens in the glass at room temperature is at the origin of the reversibility of the process, needed by most uses of photochromic glasses. Halogens serve as sinks for electrons as Ag oxidation proceeds during the fading stage.

8 Perspectives

Light absorption by colored glasses remains an area that has great potential for development in many fields. Conversely, there is a continuous interest in ultrawhite glass for solar energy and data transmission applications, with the necessity to model the parasitic absorption caused by absorbing centers. The ability to modify the speciation of transition metal ions by modifying glass composition or melting conditions is an important advantage of glasses over crystalline matrices. The chemical dependence of the structure of oxide glasses, wherein transition metal ions occupy a large diversity of sites, opens the way for selecting specific environments that will impart original coloration. The chemical dependence of the geometry and relative proportion of the sites occupied by transition metal ions may sometimes be combined with an adjustment of the oxidation states as a function of synthesis conditions. This unique feature will continue to open the way to novel colors in glass materials.

Finally, regarding historical and cultural aspects (Ch. 10.6, 10.8), spectroscopic analyses may be used to improve our knowledge of ancient glassmaking technologies. Non-invasive portable spectrometers give information on the speciation of transition elements. The investigation of stained glasses from the 12th–13th centuries, which are blue colored by tetrahedral Co^{2+} , shows that more reducing conditions were achieved in medieval than in modern furnaces, enhancing the blue color by favoring Fe as Fe^{2+} and Cu and Mn as non-coloring

Cu^+ or weakly coloring Mn^{2+} , respectively [23]. The colorimetric analysis of stained glasses confirms the skills of medieval glassmakers to master redox kinetics and develop innovative glass colors.

Photoluminescence in Glasses

Lothar Wondraczek

Otto Schott Institute of Materials Research, University of Jena, Jena, Germany

1 Introduction

Photoluminescence is an inelastic scattering process whereby a material subjected to optical illumination re-emits photons at the point of absorption [1]. The nature of the process has two important consequences: *scattering* means that the reemitted light diffuses into all directions, and *inelastic* means that the energy of the scattered photons changes. As a result, the observed wavelength also changes as does color if the process takes place in the visible range.

The phenomenon is striking in the peculiar *uranium glass*, which was most popular between the second half of the nineteenth and the first half of the twentieth century and is today found in antique shops in forms ranging from beads, vases, and plates to tableware and lampshades. Here, the strong photoluminescence gives rise to a characteristic greenish or even yellow color due to uranyl ions, UO_2^{2+} , in quantities of up to several thousands of ppm (Figure 1). Through exposure to sunlight (or, for better visibility, to an ultraviolet [UV] lamp), it can be readily distinguished from other glasses of similar color such as yellowish-brown uranate glasses (e.g. containing $\text{U}_2\text{O}_7^{2-}$), which are not luminescent. Also in practice, photoluminescence is routinely used to distinguish between the tin and airside of float glass (Chapter 1.4) because impurity divalent tin ions, Sn^{2+} , can be electronically excited by exposure to UV light: relaxation of this excited state back to the ground state occurs radiatively whereby a pale, bluish shine can be observed.

Today, however, the most important applications of photoluminescent glasses deal with optoelectronics. The purpose of this chapter is thus to review the basic physics that is needed to understand how such applications are designed. The fundamentals of photoluminescence and inelastic light scattering will first be presented. How glass chemistry can be engineered to optimize the phenomenon will then be described. Finally, key parameters such as quantum efficiency or emission lifetimes will be discussed.

In preamble, it may be useful to state how whether or not a certain glass exhibits visible or infrared photoluminescence can be determined from the electronic properties of its chemical components, in particular, of its minority species and dopants. Consider, for example, sodium oxide, Na_2O , an archetypal constituent of silicate glasses (Figure 2a). With eleven electrons, the sodium atom has the configuration $1s^2 2s^2 2p^6 3s^1 = [\text{Ne}]3s^1$. That is, one electron on the 3s orbital is only loosely bound and can thus be readily excited, for example, to 3p or other higher-lying states. In sodium gas, relaxation from 3p occurs through emission of a “yellow” photon according to the energy gap between the 3p and 3s states. This process is the basis for sodium-vapor gas discharge lamps (Figure 2b).

In glasses, however, sodium is clearly not incorporated in its atomic form, but in the oxidized Na^+ state in which the $3s^1$ electron is missing. The energy provided by visible (or UV) light is not sufficient to excite one of the deeper-lying 2s or 2p electrons so as to provide for photoluminescence. In contrast, X-rays can be employed for this purpose, which is why X-ray fluorescence is so commonly used for chemical analyses of glasses and other materials (Chapter 5.1). Obviously, weakly bound electrons are necessary, but not sufficient, to generate a visible photoluminescence in glass. These are available when the material contains Sn^{2+} , UO_2^{2+} or a multitude of other optically

active ions within specific concentration limits. In their ionic form, some of the most prominent elements that may cause photoluminescence in glasses are summarized in Table 1. These are the transition metals, with their weakly bound outer d-electrons, and the rare earths. Among them the divalent manganese ion, Mn^{2+} ($[\text{Ar}] 3d^5$), is the most commonly involved in the photoluminescence of natural minerals and has also made its way into some artistic or decorative glass products, although less prominently, generating an attractive deep red-dish shine.

2 Inelastic Light Scattering Through Photoluminescence

A beam of light with a wavelength appropriate for luminescence excitation can literally be seen, but at the specific color of luminescence, whereas this very same beam remains fully invisible in a neutral glass as long as there is no scattering toward the observer's eye. In Figure 3, a green (right, bottom) and a red (right, top) laser beam are guided through two blocks of transparent material. One (right) is a glass doped with ~ 500 ppm of trivalent europium, Eu^{3+} , and the other is a glass ceramic (Chapter 7.11) with a crystal size of ~ 30 nm and a crystal volume fraction of $\sim 80\%$. In the glass specimen, the green laser excites Eu^{3+} species to emit red (fluorescent) light, visible to the observer. The red laser beam is not seen because it is scattered neither inelastically nor elastically. In the glass ceramic specimen, both beams are scattered elastically at the glass–crystal interfaces although the red one is scattered to a lower extent because of its higher wavelength relative to the crystallite size.

Physically (Figure 4), photoluminescence in Eu^{3+} -containing glasses involves various sharp bands that result from the intra-configurational $4f \leftrightarrow 4f$ parity-forbidden electronic transitions from the Eu^{3+} excited state of $^5\text{D}_0$ to the states of $^7\text{F}_J$ ($J = 0, 1, 2, 3, 4$) (Figure 4c). As discussed later, the local structural environment does not notably affect the energetic location of the transitions since the involved f-levels are well shielded from the surrounding anions. The probability of certain relaxation reactions is strongly affected by the ligand symmetry, however, which represents a useful

Figure 2 Electronic transitions in sodium. (a) Electronic configuration of atomic sodium, $[\text{Ne}]3s^1$, providing for a characteristic yellow luminescence. (b) Photoluminescence whereby an incoming photon creates a state of excitation (i), which relaxes non-radiatively through a series of narrow jumps until the emission level is reached (ii). From the emission level, relaxation occurs predominantly radiatively, i.e. through emission of a photon (iii) to a deeper-lying basin within which further non-radiative transitions may occur (iv).

structural probe. Technical applications rely on the broad absorption band of Eu^{3+} in the 350–420 nm spectral region (Figure 4a), which makes Eu^{3+} (and its divalent counterpart) one of the most prominent optical activators in solid-state phosphors [2]. In this context, glasses as host materials offer potential advantages such as very high compositional flexibility, simple and low-cost manufacture, versatile forming technologies, superior thermal stability, and epoxy-free assembly processes. But these advantages usually go at the expense of the absorption cross section and quantum efficiency of luminescence, which results in potentially low quantum yield. Oxide glasses are, therefore, currently not used as phosphor materials.

There is a variety of photoluminescence schemes (Figure 5; see also [3]). Often depending on the desired material properties, glasses can be – at least in theory – tailored through different combinations of matrix glass

composition to which one, two, or more optically active species are added. In each case an incoming photon generates an excited electronic state before the ground state is recovered along a certain relaxation path that involves radiative and non-radiative transitions. The latter for example occur through energy transfer to the surrounding lattice by the creation of phonons, or through excitation of electrons of other optically active species. In the simplest case (Figure 5a), after excitation, part of the absorbed energy decays non-radiatively, and the remaining part causes the emission of a new photon. The energy of this new photon is always lower than that of the incoming photon, i.e. its wavelength is longer.

As an important extension of such a three-level system, the four-level system (Figure 5b) involves two non-radiative steps in between which the radiative transition is embedded. As discussed later, this case is especially relevant to laser-active materials because it allows for the so-called inversion of band occupation [4]. In some cases, a single photon of high energy may trigger the emission of two (or even more) secondary photons through a radiative cascade process (Figure 5c). This process presents an intriguing feature as it offers the possibility to enhance the quantum efficiency of the luminescence process to beyond 100 %. Vice versa, the excitation scheme can also be tailored, so two photons contribute to the excitation (Figure 5d). Materials offering such properties have been receiving much attention because they enable photons to be converted from lower (e.g. infrared) to higher energy through an *upconversion* process. Like two-photon process, however, upconversion suffers from a notoriously low efficiency.

In many cases, the absorbing and emitting ions are not the same [5]. For example, a sensitizing species can be used to ensure adequate absorption in a certain range of wavelengths (Figure 6). The absorbed energy is then transferred to a secondary dopant species, which provides the desired emission properties (Figure 5e). In a practical application, clearly the sensitizer and emitter must be

Figure 4 Spectral characteristics of photoluminescence from Eu^{3+} -doped glasses. (a) Typical excitation spectrum, with an emission band at 612 nm (cf. text). (b) Corresponding emission spectrum for excitation at 394 nm, including emission from higher-lying states (inset). Underlying energy level diagram given in (c).

Figure 5 Different schemes of photoluminescence: (a) downconversion in a three-level system, (b) four-level system, (c) cascade emission, (d) upconversion, (e) energy transfer, and (f) quantum cutting.

Figure 6 Sensitization through co-doping: an efficient absorption in a certain spectral range is achieved through a suitable co-dopant species. From this species, the absorbed energy is transferred to the primary emitting species, thus increasing the range of spectral sensitivity of the latter.

chosen carefully on the basis of their electronic structures to ensure efficient energy transfer. If the excitation energy is high enough to be transferred to two or even more secondary emission centers, as done in cascade emission, an efficiency higher than unity can be obtained through the so-called quantum cutting (Figure 5f).

3 Photoluminescence and Glass Chemistry

The chemical design of photoluminescent glasses typically addresses two aspects: the choice of a proper ensemble of optical activators and the search for a suitable matrix material. The activator may be a single dopant at a given concentration or a combination of multiple dopants with different functions (sensitizer, amplifier, emission center, etc.; e.g. Figure 6). Here, the immediate parameters of interest are the spectroscopic properties, that is, the excitation and emission schemes, excited state lifetime, and quantum efficiency. Secondary parameters may, for instance, include the temperature dependence of photoemission, saturation effects and the power dependence of the emission intensity, or cross-reactions such as excited state or anti-Stokes emission.

All these properties depend on the matrix chemistry whose choice thus is also an important feature. Especially important in this respect is the ability of the glass matrix to dissolve the activator species at sufficiently high concentrations without triggering phase separation, clustering, or crystal nucleation. In addition, specific redox conditions are needed to stabilize the desired oxidation state (Chapter 5.6) and to secure the absence or specific presence of photooxidation or photoreduction reactions, whereas the matrix composition should ensure appropriate ligand configurations (ligand chemistry, crystal field

strength, coordination, and symmetry) and phonon energy (i.e. the possible avoidance of non-radiative relaxation that would counteract photoluminescence).

Typically, glass matrices with low phonon energy are sought, e.g. tellurites, fluorides, or fluorophosphates (cf. Chapter 6.5), in which non-radiative relaxation involves the concerted action of multiple phonons and, thus, becomes less and less probable. One should not disregard seemingly secondary glass properties, however, because in practice they may play a still more important role. For example, the possibility of fiber drawing largely relies on viscosity and liquidus temperature or on the absence of crystallization upon heating above the glass transition temperature (Chapter 6.5). The thermal expansion of the glass may become problematic in high power applications if it causes the formation of mechanical stress (Chapter 3.12). As for the refractive index, Abbe number, and thermal dispersion (Chapter 6.1), they determine the numerical aperture and thermal lensing effects during laser operation or the efficiency of light extraction. Finally, nonlinear optical effects determine the damage threshold for potential laser glasses. Because these features are discussed in other chapters, however, here the focus will be placed on the activator species and the resulting mechanism of photoluminescence.

Some typical elements that may play a role as activators or sensitizers in photoluminescent glasses have already been listed in Table 1. Like the sodium counterexample in the glass matrix (Figure 2), they are usually present in oxidized forms, i.e. with one or more of the outer electrons missing. The remaining electronic configuration determines the actual optoelectronic properties as already discussed for the archetypal case of Eu^{3+} (Figure 4). The origin of photoluminescence from the latter is an $f-f$ transition. As seen from Table 1, such a transition is shielded from the environment by the outer 6s orbital. A typical consequence is the very low dependence

of spectral band position on ligand situation, that is, matrix chemistry and activator coordination. The photoluminescence emission bands are, therefore, characteristically narrow as exemplified by Eu^{3+} -, Tb^{3+} -, or Er^{3+} -doped glasses. This feature is common among many of the rare earth activators in which f - f luminescence bands are observed. The excited state positions of the most relevant trivalent rare earth species are summarized in Figure 7. These cover the elements from cerium to ytterbium (with the exception of the unstable radioactive promethium, Pm^{3+}). In addition to the trivalent states, other oxidation states are also of importance in glassy materials for some rare earth elements, e.g. Eu^{2+} , Yb^{2+} , and Sm^{2+} . In tetravalent Ce^{4+} , all outer electrons are missing, so, as for Na^+ , neither color nor photoluminescence is typically observed. Although the latter species are not considered in this chapter, we note that not only f - f but also other types of transitions may occur, in particular, f - d , in such redox states.

Whereas the resonance energy of an f - f transition is typically independent on crystal field strength, the transition probability between some of the degenerate states depends on ligand symmetry through its effects on orbital distortion. As a result, the intensity ratio among certain emission peaks is a function of local symmetry. Hence, rare earth elements can be used as highly sensitive and extremely local structural probes, even in cases where other techniques such as X-ray diffraction fail to provide useful information. In addition to the f - f transitions, f - d or d - d transitions can be exploited in rare earth ions with lower valences or in transition metal ions. Here, splitting of the d -levels is strongly affected by the type and number of ligand species and, thus, matrix composition. In the

example of trivalent chromium in a phosphate glass matrix (Figure 8, [6]), Cr^{3+} has the electronic structure of $[\text{Ar}]3d^3$, that is, three electrons on the outer d -level. If Cr^{3+} is integrated into a solid matrix, interaction with the surrounding ligands leads to crystal field splitting. The degree of splitting depends on the strength of the crystal field, i.e. on the coordination number, symmetry, and type of anions. At a given field strength (Figure 8), a certain order and energetic position of all possible states is achieved. In the present case, the corresponding optical absorption spectrum is dominated by two broad absorption bands that are associated with the characteristic $^4A_2 \rightarrow ^4T_1$ and $^4A_2 \rightarrow ^4T_2$ transitions. A zoom on the red region reveals a further, weaker band corresponding to $^4A_2 \rightarrow ^2T_1$ and $^4A_2 \rightarrow ^2E$ transitions. Photoemission occurs in the near-infrared (NIR) spectral region.

The Tanabe–Sugano diagram is usually applied for a quantification of the effects of field strength on the electronic structure of d -elements [7]. It uses the Racah parameter B and a crystal field parameter, denoted D_q , to scale band energy and field strength. For Cr^{3+} (and also many other d -ions), an interesting question is that of the dependence of the lowest excited state (from which luminescence is expected) upon crystal field strength: here, one finds that an intermediate octahedral field of approximately $2.1 < D_q/B < 2.3$ typically separates the low and high field regions. Between those two regions, the emitting state is either 4T_2 or 2E , whereby only the 4T_2 state is very sensitive to D_q/B (Figure 8). When the Cr^{3+} ion locates in a weaker ligand field environment, the 4T_2 level is lower than the 2E level, which then results in a broad-band emission arising from the spin-allowed $^4T_2 \rightarrow ^4A_2$ transition. In contrast, when the Cr^{3+} ion locates in a

Figure 7 Excited state configuration of various trivalent rare earth ions. The arrows indicate some emission reactions that have received attention for NIR lasing activity or other purposes (labels indicate emission wavelength). Pm^{3+} , positioned between trivalent Nd and Sm, not shown.

Figure 8 Photoluminescence from Cr^{3+} in a phosphate glass matrix (simplified). Depending on ligand field strength, ${}^4\text{T}_1$ and ${}^4\text{T}_2$ are split to different extent, which results in the characteristic variations in Cr^{3+} -related glass color. Photoluminescent reemission occurs from the lowest excited state.

strong crystal field, the ${}^2\text{E}$ level falls below the ${}^4\text{T}_2$ level, and, thus, the spectrum exhibits the sharp *R*-line originating in the spin-forbidden ${}^2\text{E} \rightarrow {}^4\text{A}_2$ transition (such as in the very prominent example of crystalline ruby lasers in which Cr^{3+} precipitates in the strong ligand field of Al_2O_3). Similar effects can be exploited in many of the d-element activator species for which the emission characteristics of a given redox state vary widely with the field strength.

Beyond very popular rare earth and transition metal ions, certain activator species have been reaching a level of significant research activity for application in glasses. Here, the most prominent recent example is bismuth in its various oxidation states (Figure 9). A major interest in this species was initiated by the discovery of broadband

photoluminescence in the NIR spectral region of Bi-doped silica glass [8]. Involving a broad variety of host glasses, subsequent studies have shown that this emission band covers the major part of the telecom spectral range, i.e. the range of wavelengths within which optical data are transmitted. For such data transmission, optical amplifiers are required to enable photoemission to be stimulated optically in the relevant spectral range. Today's benchmark material is the Er^{3+} -doped fiber amplifier (EDFA), which relies on the luminescence properties of trivalent erbium (Figure 7). It provides a unique set of properties, so it has an unchallenged efficiency in optical amplification around the $1.5\ \mu\text{m}$ spectral range [9]. This is also the range where vitreous silica fiber exhibits the lowest optical loss (Chapter 6.4), thus making it a perfect

Figure 9 Simplified representation of the electronic states in some optically active ion species of bismuth.

match for long-range optical communication. But a problematic feature has been the limited spectral bandwidth yielded by the fundamental nature of the underlying f–f transitions in Er^{3+} . Here, the discovery of ultrabroad NIR emission from Bi-doped glasses has been considered as offering a promising alternative although technical demonstrations have not yet been successful. Interestingly, the fundamental origin of NIR photoemission from Bi-doped glasses remains highly debated [8].

Taking a broader look at bismuth in glasses, one notices that the multiplicity of redox states in which the bismuth ion (or ion cluster) may be present allows for a broad variety of materials with fundamentally different optical activities. In Figure 9, only the archetypal cases of Bi^{3+} , Bi^{2+} , and Bi^+ are shown. With decreasing number of electrons, the electronic band gap of these species increases, so photoluminescence occurs at increasingly high energy (low wavelength). In all three redox states, however, the transition energies depend very strongly on crystal field, so the emission properties are also highly matrix dependent. The most common form of bismuth in glasses is Bi^{3+} , which usually exhibits blue or green photoluminescence. Divalent Bi^{2+} , on the other hand, shows red photoemission. This contrast provides another glimpse at the rich nature of the general subject and at the enormous possibilities existing to generate a specific photoluminescence in an appropriate glass matrix.

4 Efficiency, Lifetime, and Quenching Effects

The *quantum efficiency* is a key parameter in many applications of photoluminescence. It is in addition fundamental to understand physically the underlying relaxation process that finally leads to photon emission. It describes the ratio between the numbers of emitted and absorbed photons, that is, the probability that absorption of one single photon actually causes the photoluminescent emission of a secondary photon. That this probability is by definition lower than unity signifies that the relaxation scheme of Figure 2b represents only an ideal case: coexisting with photon emission (*radiative decay*), other relaxation pathways may be followed, in particular phonon excitation or energy transfer.

An accurate determination of quantum efficiency is not obvious. If conducted directly, it comprises determination of the absolute photon flux upon excitation and emission. Integration spheres and careful referencing are required for this purpose. The experimental approach then distinguishes between internal and external quantum efficiency, whereby the latter acknowledges the

existence of secondary effects such as the efficiency of light extraction or the occurrence of reabsorption, which also leads to a reduction in the experimentally visible intensity of photoluminescence. Efforts on materials development, therefore, often aim at increasing the external quantum efficiency.

In the specific case of glasses, however, the sole notion of quantum efficiency is often misleading in terms of practical applications because it does not provide a measure of the generated emission gain. In other words, high quantum efficiency does not guarantee high emission intensity. Regarding this parameter, the absorption cross section must also be considered so that the figure of merit is a convolution of quantum efficiency and absorption probability. Typically, this is where glasses suffer from a major drawback, i.e. they often have comparably low absorption cross section. In addition, common strategies for overcoming this problem such as increasing light–matter interaction pathlengths through multiple scattering cannot be employed because of the lack of a microstructure. On the other hand, one can increase the emission intensity either by increasing the amount of dopant or by directly enhancing the optical pathlength within the material. For both routes, glasses are particularly suitable: they can be chemically tailored to maximize the solubility of the optical activator and/or secondary dopant species, and they can be formed practically universally into any shape. In particular, in the form of optical fiber, they guarantee a maximum optical pathlength, which then often enables efficient photoluminescence even at low absorption cross sections.

Regarding the increase in dopant concentration, however, solubility is not the only requirement. The maximum dopant concentration is usually limited by the occurrence of energy transfer reactions, often denoted *concentration quenching*. Such reactions may occur over short or long spatial ranges (e.g. Foerster transfer, Dexter transfer) and always reduce quantum efficiency. The maximum dopant concentration at which the drop in quantum efficiency is observed is termed the *critical concentration*, x_c .

Some simplistic formulas have been constructed to aid in the approximate quantification of energy transfer probabilities. For example, the critical distance R_c , representing the mean spatial separation between two emission centers at x_c , is often estimated from

$$R_c = \sqrt[3]{\frac{6V}{\pi x_c N}}, \quad (1)$$

where N is the number of emission sites per unit volume V (usually taking the volume and number of sites of a unit cell for crystalline materials and the molar volume and

molar concentration for glasses). For electric dipole–dipole interactions, R_c is sometimes also estimated directly from the excitation and emission spectra:

$$R_c^6 = \frac{3 \times 10^{12} \times f}{E^4} \int f(E)F(E)dE, \quad (2)$$

where f is the oscillator strength and E the energy of maximum spectral overlap and where the integral represents the overlap of the normalized emission and excitation spectra.

In a more detailed consideration of glass structure, however, the value of R_c has only little meaning because spatial relations among the atomic constituents of the glass network are determined by bond lengths, coordination numbers, and bond angles. Especially over short ranges, they cannot be approximated through simple mean-field statistics. Instead, one may calculate the probability of cluster formation across first, second, or third coordination shells, which is approximately derived from the molar concentration of the specific ion, its coordination number, and the coordination numbers of all other anionic and cationic constituents of the system.

In many cases, an analysis of the lifetime of photoluminescence is a more suitable way to judge the probability of radiative relaxation. In a first approximation, a simple exponential relaxation function is often used to describe the rate at which the emission level is depopulated:

$$I(t) = A \exp\left(\frac{-t}{\tau}\right), \quad (3)$$

where τ is the decay time and A is a fit constant. This law assumes that the transition probability is independent of the population of the excited state. In certain cases, which are not considered here, stretched or compressed exponentials are observed instead. The value of τ represents the time after which the initial emission intensity has decreased to a fraction of $1/e$. Non-radiative relaxation occurs very rapidly through phonon activation, in particular in narrow energy quanta, so the experimentally observed lifetime of photoluminescence is decreasing with increasing non-radiative contributions. In such a case, one can decrease the probability of non-radiative relaxation by either decreasing the temperature or by increasing the number of phonons that need to be activated collectively in order to bridge the respective energy gap between the excited and ground states. This is why glasses with low phonon energy are typically sought as host species. In the theoretical case of absolute zero temperature, no phonon relaxation would occur, which would ensure a maximum lifetime in the absence of phonons. Therefore, observing the emission lifetime as a function of dopant concentration (or other chemical variations on the system) always provides some relative

information on quantum efficiency. One then uses a temperature-dependent lifetime analysis to extrapolate this information so as to obtain also absolute data, for instance, by referencing the observed lifetime to its extrapolated value at absolute zero temperature.

One can also treat electronic energy transfer processes in this way, for example, by approximating the energy transfer efficiency η_{ET} with

$$\eta_{ET} = \frac{1 - \tau_s}{\tau_{s0}}, \quad (4)$$

where τ_{s0} and τ_s represent the values of emission lifetime from an activator species in the absence and in the presence of a secondary energy acceptor species, respectively. The energy transfer rate κ_{ET} between the two entities can also be estimated:

$$\frac{1}{\tau_s} = \frac{1}{\tau_{s0}} + \kappa_{ET}. \quad (5)$$

Such considerations often provide practical tools for exploiting or avoiding energy transfer processes by chemical tailoring.

5 Applications

Because of their emission gain and other spectroscopic properties, photoluminescent glasses do not play an important role in prominent applications such as phosphors in solid-state lighting or display. But they did find niches as irreplaceable components in various specialty sectors among which optically active fiber devices and glass lasers are the most important [10, 11]. And, from a chemical standpoint, another important application of glass photoluminescence concerns probing of short-range structural features through the aforementioned dependence of spectroscopic properties on the ligand field in the vicinity of the active species. In particular for the d–d or f–d transitions, knowledge of the variation of band structure as a function of field strength (such as given in Tanabe–Sugano diagrams) enables the crystal field strength to be directly evaluated from the peak positions of the observed emission bands. For example, this allows the local energy density to be probed or bond distance and coordination number to be determined by comparisons with reference materials (Figure 8). In a less direct way, analysis of f–f transitions provides information of ligand symmetry. As a final perspective, the study of energy transfer may help to shed light also on longer-ranging structural features, including clustering and non-random ion precipitation.

Table 2 Prominent examples of laser-active glasses.

Lasing species	Laser line (μm)	Glass matrix
Er^{3+}	1.5	Fluorophosphates
Ho^{3+}	1.9	Silicate
Nd^{3+}	0.9	(Na, Ca) aluminosilicate
	1.1	(K, Ba) silicate
	1.4	(La, Ba, Th) borate
Tb^{3+}	0.54	Borate
Tm^{3+}	1.9	(Mg, Ca, Li) aluminosilicate
Yb^{3+}	1.0	(Mg, Ca, Li) aluminosilicate

Table 3 Sensitizer–activator combinations in some laser glasses.

Lasing species	Sensitizer species	Glass matrix	Molar ratio of activators	Emission peak (μm)
Er^{3+}	Yb^{3+}	Fluorophosphate	1 : 8	1.5
Ho^{3+}	Yb^{3+}	Silicate	1 : 1	1.9
Nd^{3+}	Mn^{2+}	Phosphate	1 : 1	1.1
Tm^{3+}	$\text{Yb}^{3+}, \text{Er}^{3+}$	Silicate	1 : 1	2.0
Yb^{3+}	Nd^{3+}	Borate	1 : 1	1.0

The technical applications of active optical fiber and bulk laser glasses are dominated by rare earth-doped materials. Some prominent examples are given in Table 2. The popular Nd^{3+} -doped glass lasers involve commercial products such as codes LG 660, LG 670, LG 680 (all Schott, Germany), LSG 91H (Hoya, Japan), or Q246 (Kigre, USA). Common to all laser glasses, they exhibit emission lifetimes above 500 μs (ideally at room temperature, occasionally at cryogenic temperature), sometimes reaching up to several ms such as in Er^{3+} -based systems. Typical combinations of sensitizer and activator are listed in Table 3. With the exception of Mn^{2+} in Nd^{3+} phosphate laser glasses, here as well, rare earth sensitizers are dominating.

Beyond bulk laser glasses, vitreous silica remains the most important material for optical fiber thanks to its well-established high-purity processing schemes and the underlying materials logistics (Chapter 6.4). Consequently, optically active fiber relies on rare earth-doped silica. The dopants includes Er^{3+} for telecom fiber amplifiers [12], Yb^{3+} for high power lasers [13], and further species analogous to those shown in Table 2 for the farther infrared [14].

6 Perspectives

Photoluminescence is a peculiar phenomenon that unfolds particular beauty in glasses. *Shining from within*, this very attractive visual effect results from the combination of inelastic scattering and optical transparency and may be put to use in many ways in art and design, consumer glass products, fluorescent glazes and enamels, or fiber-illumination sources, which are beyond the scope of this chapter. But glasses are not always ideal materials for more technical applications, in particular, when one needs high emission gain, high absorption cross section, elastic scattering and light diffusion, or color quality and stability. In some niches such as optical fibers, however, luminescent glasses have become indispensable materials. Here, exploitation of the emission and excitation properties of transition metal dopants and other optically active species beyond the rare earths remains a field of challenge. In other, more exploratory areas, interesting devices, and design studies continue to evolve, including luminescent concentrators, light-emitting fibers, or three-dimensional displays.

1 Introduction

Whether in physical or biblical contexts, light has been illuminating the universe since its beginnings. As reviewed in Chapter 10.10, the first substantive scholarly efforts at describing light can be attributed to Euclid of Alexandria (*Optica*; ca 300 BC), Claudius Ptolemy (*Optica*, ca 150 AD), and later to such luminaries as Abū ‘Alī al-Ḥasan ibn al-Haytham (*Book of Optics* written in the 1010s), René Descartes (*Dioptrique* in 1637), Robert Hooke (*Micrographia* in 1665), Isaac Newton (*Opticks* in 1704), and James Clerk Maxwell (*A Treatise on Electricity and Magnetism* in 1873). Indeed the millennial anniversary of Ibn al-Haytham’s opus was one of several reasons for 2015 being celebrated globally as UNESCO’s *International Year of Light*.

As relates to optical fiber, the operative principle governing light confinement and propagation is that of total internal reflection taken in a ray-optic construction. Total internal reflection was first described by Johannes Kepler in 1611, mathematically described by Willebrord Snellius (1580–1626), and eventually popularized in the mid-nineteenth century through the giant luminous fountains invented by Jean-Daniel Colladon [1] on the basis of total reflection of light at the air–water interface (Figure 1). Even though the same phenomena were observed at the same time in meter-long bent rods drawn from crown glass by Jacques Babinet [2], the potential of optical fiber would still not be more fully appreciated for nearly another century. Not until,

that is, the advent of the laser as a coherent and collimated light source and the description of materials and loss mechanisms in waveguides at optical frequencies [3]. The latter work earned Charles Kao the Nobel Prize in Physics in 2009 for “groundbreaking achievements concerning the transmission of light in fibers for optical communication.”

A global race ensued to develop optical fiber with sufficiently low loss such that (laser) light could efficiently propagate over long distances and enable high-speed and high-capacity communications. As detailed below, these goals required, at least as relates to the glasses, a wide variety of innovations that included optimized glass compositions, glass and fiber fabrication processes, and light-amplifying and optically nonlinear fibers, the specifics of which are all application specific. Though applications do abound, some of which are described below, the present and near future use of glass optical fibers remain dominated by telecommunications, at least on a volume basis. For this reason, this chapter will largely focus on the glasses and processes associated with communications. At the time of the printing of this *Encyclopedia*, the global production of optical fiber for communications exceeds 10 m per year for every person on Earth.

The performance of an optical fiber most strongly depends on the optical properties of the constituent glasses and on the design of the fiber itself. These topics will be described first, without delving into other thermal, mechanical, or chemical properties of practical interest that are adequately dealt with in other chapters. The most common glass families employed in making practical optical properties are then discussed before the main fabrication processes used are reviewed. Finally, a variety of applications of optical fibers are briefly presented.

2 Optical Properties and Fiber Designs

2.1 Optical Properties

2.1.1 Dispersion, Absorption and Scattering

The vast majority of optical fibers are passive in that they serve as hair-thin conduits that simply transmit light from one place to another. As with any property, the efficiency with which fibers perform this task depends upon both intrinsic and extrinsic factors. Given the maturity of optical fiber fabrication, extrinsic factors such as bubbles, striations, and inclusions will be neglected. Impurities, however, are critical impediments since they absorb light in a way that can have great impact on long-distance communication links. Given the spectral bands of significance for the primary optical-fiber applications, the most detrimental impurities tend to be hydroxyl groups, $-OH$, and transition metals, most notably iron (Fe^{2+}) and copper (Cu^{2+}).

Intrinsically, the canonical optical property of any material is the index of refraction (cf. Chapter 6.1). It is a relative measure of the speed of light in vacuum, c , to that in the material, v , such that $n = c/v$. Macroscopically, a general expression for the refractive index can be derived from the Newtonian dynamics of a mass/spring system under the influence of an applied field (i.e. the electric field of light). The electric field intensity of light varies as a sinusoid in time (and position), and so the dielectric displacement of the charged species within the glass follows this polarization. At optical frequencies, the relevant charged species that define the properties of optical fiber are the electrons (in the ultraviolet) and the ions/molecules (in the infrared). Further details on the macroscopic derivation of the refractive index can be found in any introductory optics or optical materials text [4].

Since the polarization of the electrons and/or ions is frequency dependent, so is the refractive index: this dependence of index upon frequency or wavelength (λ) is called the chromatic dispersion. Though not the focus of this Chapter, it is an important consideration in telecommunication optical fibers since data signals are composed of a small range of wavelengths. Since each wavelength experiences a slightly different refractive index, hence velocity, the signals spread over time (distance) and can ultimately overlap such that information is lost. For this reason, early systems were designed to work at the zero dispersion point, which for silica glass optical fibers is at a wavelength of about $1.3\ \mu m$ [4, 5]. Microstructured and photonic crystal optical fibers possess dispersion properties that can be tailored via specific fiber design (Figure 2). This latter point is useful since the waveguiding properties, such as loss and dispersion, of an optical fiber depend both on the materials from which it is made as well the waveguide design itself.

Within the spectral bands of conventional (bulk) optics, the refractive index of conventional glasses and optical fibers decreases with increasing wavelength (normal dispersion). As the interaction between the electric field of the light and the charged species is one of a damped resonance, there are frequencies or wavelengths where dielectric relaxation is approached. At this frequency, the dispersion becomes anomalous, and the glass becomes highly absorptive. The reason is that the refractive index is a complex function whose real part is what is typically thought of as the index of refraction and the imaginary part the absorption. Accordingly, since the refractive index changes with wavelength, so too does the absorption or, more importantly for optical fibers, the absorption per unit distance, called the attenuation (typically given in units of dB/km).

As noted, absorption caused by electrons and ions/molecules occurs in the ultraviolet and mid-infrared

Figure 2 Dispersion curves for silica (top) and for selected MOF/PCF fibers (bottom). Source: Reprinted with permission from [5].

ranges, respectively. In between, i.e. in the visible and near-infrared, glasses are intrinsically transparent and have potentially low attenuation. This feature is especially useful for long-haul, fiber-based telecommunication systems since the greater the distance light can travel through a fiber, the fewer amplifiers are needed to ensure that the optical signals arrive at their destination, the result being a simpler and less costly system. In addition to absorption, light can also be partially scattered by minute density fluctuations in the glass. Given that the size of the structural units causing the scattering is very small compared with the wavelength of light, the process at work is Rayleigh scattering with an intensity that depends on wavelength as λ^{-4} . The process is generally considered a source of attenuation for transmission by a fiber over a given distance because the light can be redirected even though it is not absorbed owing to the elastic nature of the scattering.

Accordingly, the intrinsic transparency of a glass optical fiber is defined by the absorption of electrons in the ultraviolet, Rayleigh scattering in the visible and near-infrared, and absorption by ions/molecules in the

Figure 3 “V-curves” of theoretical attenuation as a function of wavelength for selected optical fiber materials.

mid-infrared, which differs for each glass composition. A plot of loss as a function of wavelength yields a “V-curve,” so designated from the shape of the curve (Figure 3). Because of the maturity of the chemical vapor deposition process, the lowest loss optical fiber realized to date remains conventional telecommunication-grade silica.

2.1.2 Active Optical Properties

Though quite a few ions can generate light upon suitable excitation when doped into glass, the rare earths are the most commonly used because their $4f$ electrons yield efficient and narrow linewidth emissions thanks to their efficient shielding by outer lying $5d$ states. The amorphous structure of glass promotes inhomogeneous broadening of the rare earth dopant absorption and emission lines, however, which was originally thought to preclude the possibility of laser action. But the concern proved to be wrong as it was not long after that the first experimental realization of lasing by T.H. Maiman in 1960 with ruby ($\text{Cr}^{3+} : \text{Al}_2\text{O}_3$) and the first glass-based laser were reported [6].

This first glass laser employed neodymium (Nd^{3+}) as the active dopant in a barium crown glass (N.B. a dopant is a small but important value-added constituent to the composition, whereas the presence of an impurity generally is unintended and unwanted). Since then, virtually all of the rare earth ions have been made to lase [7].

The glass host plays a critical role in determining which transition, hence wavelength, is involved and how efficient the laser action is. To first order, selection of the active dopant is based on the separation of its energy levels and on whether this difference is equivalent to the energy of the desired emission. Electrons from the ion's ground state are excited into the necessary state via optical pumping of light. The energy of this optical pump is resonant either with the excited state from which the emission occurs or with an excited state of energy higher than it, followed by relaxation into the desired excited state. Admixing of opposite parity states breaks the symmetry restrictions that would otherwise preclude emission from intra- $4f$ transitions: as such, the rare earths are considered weakly coupled to the host. The benefit of this weak coupling is the aforementioned narrow spectral linewidths as well as the possibility for fairly long-lived electron populations in the excited states prior to de-excitation. These excited state lifetimes, which can be of the order of micro-, through several milli-seconds, provide a metastability that facilitates the population inversion central to lasing.

An electron in a metastable excited state will de-excite either radiatively or non-radiatively. Without external stimulus, the relaxation is spontaneous in the former (light-emissive) case. With an external stimulus, which would most likely be a photon for dielectric glasses, then the relaxation is stimulated provided that the photon has an energy equal to the energy difference between the populated excited state and a lower lying level. For spontaneous emissions, the light given off has no correlation in direction, polarization, or phase to any other spontaneous emissions that may occur within the host at the same time, and its energy is the difference between those of the originating and terminal electron levels. For stimulated emission, the generated photon is, in contrast, identical in all ways (direction, energy, polarization, and phase) to the photon that stimulated it. This creation of equivalent photons is a hallmark of the laser process.

Further, if the stimulating and stimulated emissions are permitted to leave the host after a single pass, then the process is considered as optical amplification. If the stimulating and stimulated emissions are fed back into the host via some reflective structure in order to intensify further, then one denotes this an oscillator. Both amplifiers and oscillators are forms of lasers. The glass host is critical in the efficiency of the laser for several reasons. First, lasing requires gain that cannot apply until sufficient light is provided to offset losses, such as those from impurities or scattering sites. Accordingly, laser glasses and fibers should be of highest transparency, hence purity and homogeneity. Second, in addition to fundamental properties associated with the specific transitions of each rare earth, the so-called selection rules, the probability for a

radiative relaxation scales super-linearly with the refractive index of the host. In other words, all other things being equal, the most efficient laser hosts are glasses with the highest refractive indices.

In the case of non-radiative relaxation of the excited state electrons, heat is generated rather than light. Here host phonons stimulate the de-excitation and creation of additional phonons. As such, the host glass composition is of great consequence since the interatomic bonds, and their structural arrangement, determine the phonon spectrum. Of particular importance is the highest energy (longitudinal optical, LO) vibrational modes since they involve the phonons most responsible for facilitating non-radiative relaxation. In order to reduce non-radiative relaxations, glasses can be cooled since the phonon occupancy number (number of phonons of given energy) depends on temperature and follows Bose–Einstein statistics. Alternatively, glasses with heavier and more weakly bound atoms/ions would possess lower phonon energies and therefore would exhibit reduced non-radiative relaxation rates. More specifically, heavy metal oxides, fluorides, and chalcogenides would therefore be more radiatively efficient than conventional silica-based glasses, all other things being equal.

The glass composition has yet another influence on the active performance of optical-fiber amplifiers and lasers. Whereas it would normally stand to reason that more light-emissive dopant would yield more light, there is an optimum concentration for the rare earth dopant in a given glass. There are principally two reasons for this. The first relates to glass stability. Whereas phosphate and fluoride glasses tend to be highly multicomponent, and therefore more amenable to higher concentrations of any one species, most other conventional glass families – and particularly the silicates – generally have a fairly low “solubility” for rare earth ions prior to liquid–liquid immiscibility and phase separation. Other species, most commonly alumina (Al_2O_3), are added to reduce the immiscibility range (Chapter 5.2) and permit a greater concentration of rare earth dopants into the silica.

The second reason for an optimum concentration of rare earths is the phenomenon called concentration quenching whereby electrons from one dopant can interact with electrons and energy levels of a second dopant if said dopants are in reasonably close proximity; this happens to a greater extent probabilistically as doping concentrations increase. In the specific case of concentration quenching, excited state electrons move from dopant to dopant until, as is likely, they encounter an impurity, are absorbed, and can no longer contribute to the generation of light. In order to determine the concentration-quenching limit, the radiative lifetime of a given transition is measured as a function of dopant level in a given glass. The lifetime will remain constant until the

quenching limit is reached and the lifetime will rapidly decrease with any further increase in concentration. The ideal composition for most amplifier and laser applications is where the lifetimes are the longest just before the onset of quenching. Other ion-ion interactions may also take place at higher concentrations, including cross-relaxation and cooperative upconversion which can be either detrimental or actually useful in certain applications. For example, the cross-relaxation of thulium (Tm^{3+}) in silica at concentrations in excess of about 4 wt % permits quite efficient emissions at a wavelength of 2 μm when this ion is pumped at a wavelength of about 780 nm. Thulium-doped fiber lasers have exceeded 1 kW in output power, and the 2 μm is considered “eye-safer” for defense applications.

As with the first glass laser, the first optical fiber amplifier employed Nd^{3+} as the active dopant. A critical breakthrough occurred 25 years later when an optical fiber based on erbium (Er^{3+}) doped into silica was realized [8]. The importance of this finding was that Er^{3+} can efficiently amplify light in the 1550 nm range, which overlaps the aforementioned minimum attenuation spectral window for silica optical fibers. Hence erbium-doped fiber amplifiers (EDFAs) provided a means to boost all-optical signals in low-loss silica optical fibers and helped usher in global communications as it is known today.

A comprehensive compilation on various rare earth-doped fiber-based optical amplifiers and lasers is provided in [7]. Additionally, [9] reviews fiber- (hence glass-) based lasers for high-power (>1 kW) applications where additional complexities and systems-level considerations exist. The demands on the robustness of the glass and structure and performance of the resultant fiber are accordingly significant.

2.1.3 Nonlinear Optical Properties

Generally speaking, the previously discussed passive and active optical properties of glasses are termed linear phenomena because a linear relationship exists between cause and effect. For example, a change in the pump power incident on a glass laser will result in a linear change in the output power. The ratio of input to output is almost never unity owing to losses and inefficiencies in the system, but the changes generally are linearly related. Nonlinear effects are, in contrast, defined as ones where changes between input and output are not linearly related. With specific regard to optics, nonlinear optical properties derive from the same macroscopic mass/spring consideration as linear optics, but higher-order terms are included to account for real anharmonicity in interatomic bonds.

The refractive index, or, more appropriately, the dielectric susceptibility, is expanded as a power series in electric field as $\mathbf{P}_i(t) = \epsilon_o(\chi_{ij}^{(1)}\mathbf{E}_j(t) + \chi_{ijk}^{(2)}\mathbf{E}_j(t)\mathbf{E}_k(t) + \chi_{ijkl}^{(3)}\mathbf{E}_j(t)$

$\mathbf{E}_k(t)\mathbf{E}_l(t) + \dots)$, where $\mathbf{P}$ is the polarization (dipole moment per unit volume) vector as a function of time, t , driven by the electric field, $\mathbf{E}(t)$, vector of the light. The $\chi^{(n)}$ values are the linear ($n = 1$) and nonlinear ($n > 1$) susceptibilities. The linear refractive index, n , is related to the linear susceptibility as $n = (1 + \chi^{(1)})^{1/2}$. The amorphous structure of glass precludes even-order nonlinearities for reasons of symmetry though they can be present in acentric crystals. Accordingly, the polarization as a function of electric field given above can be recast in terms of refractive index, n . For glasses this is given by $n = n_o + n_2I$, where n_o is the linear refractive index, n_2 is the nonlinear refractive index, and I is the intensity of the light, which is proportional to $\mathbf{E}^2(t)$.

The more common nonlinear optical phenomena present in glass optical fibers include frequency-mixing processes such as third-harmonic generation (THG), sum-frequency generation (SFG), difference-frequency generation (DFG), optical-parametric amplification (OPA), and other nonlinear processes, such as the optical Kerr effect, self-focusing, self-phase modulation (SPM), optical solitons, cross-phase modulation (XPM), four-wave mixing (FWM), stimulated Raman scattering (SRS), stimulated Brillouin scattering (SBS), and multi-photon absorption.

Even in their earliest days, optical fibers provided a practical proving ground for understanding and utilizing nonlinear optical phenomena. The reason is that optical fibers possess two key attributes of value to nonlinear optics: long lengths over which weak effects can grow in magnitude and small core sizes that confine the light in a reduced cross-sectional area, thus greatly increasing the optical intensity (power per unit area). Interestingly, whereas nonlinear features were originally considered to be parasitic, Stolen [10] noted with respect to modern communication systems that “Fiber nonlinear optics has grown from a novel medium for the study of nonlinear optical effects, through a period where these effects appeared as system impairments, to the present day where optical nonlinearities are an integral part of high-capacity optical systems”.

2.2 Optical Fiber Designs

As a general rule, fibers are cylindrical structures whose lengths greatly exceeds their diameters. For conventional (e.g. telecommunications) optical fibers, lengths can range from meters, as for data centers, to thousands of kilometers, as in transoceanic cables. In these cases, the diameters are prescribed by convention as having an outer cladding glass diameter of 125 μm and a core diameter that depends on whether or not only a single waveguide mode propagates (core diameters of about 8 μm with numerical aperture of about 0.14 for typical communication wavelengths) or multiple ones do (core diameter

Figure 4 (a) Total internal reflection, single/multi- and GI fiber designs, (b) electromagnetic modes, and (c) schematic designs of photonic crystal fiber and MOF. Source: Reprinted with permission from [5].

of 62.5 μm). The fibers are doubly coated with protective polymers to resist abrasion and reduce the effects of bending such that the total fiber diameter is about 250 μm . A series of images exemplifying current standard and specialty optical fibers are provided in Figure 4.

2.2.1 Conventional Core–Clad Optical Fibers

As noted above, in the ray-optic view, optical fibers guide light via total internal reflection whereby the light is confined in the high-index core, which is surrounded by a

lower-refractive index cladding. Under this condition, i.e. light incident from a high-index region into a lower-index region, Snell's law for light refraction is violated when the angle of incidence exceeds a critical angle (given by $\sin^{-1}(n_{\text{clad}}/n_{\text{core}})$, where n_{clad} is the refractive index of the clad and n_{core} is the refractive index of the core, and reflection, instead of refraction, occurs (Figure 4a). The index difference between core and clad need not be large and actually is one of the design parameters that define the behavior of the resultant waveguide.

For simple descriptions, the ray-optic picture generally suffices. For more sophisticated designs, however, light is more correctly described as a wave, and the aforementioned ray-optic construction is replaced with a wave-optic formalism in which electromagnetic modes are confined and allowed to propagate within a higher refractive index core coaxially surrounded by a lower-refractive index cladding. In the wave-optic perspective, the transverse components of the light waves constructively and destructively interfere across the core, influenced by the cladding, yielding stable propagating fiber modes. Some of the light power inevitably extends into the cladding: this component is called the evanescent field. The exact distribution of these modes depends on the core size, refractive index contrast between core and clad (defined by the numerical aperture, $\text{NA} = [n_{\text{core}}^2 - n_{\text{clad}}^2]^{1/2}$), the wavelength of light, and the cross-sectional geometry of the core; i.e. whether rectangular, circular, elliptical, etc. Thorough reviews of conventional core/clad optical fiber designs are given in [5, 11].

One important practical consequence of the coexistence of modes in an optical fiber is modal dispersion. In communication systems, the optical fibers carry a digital (on/off) series of packets of light. Because each mode has a different distribution, it has a different effective (mode) index, hence velocity. As a result, data packets launched into a fiber that excite multiple modes will necessarily spread in time, analogously to the chromatic dispersion of pulses noted above, such that data can be lost over time/distance. Such multimode (MM) optical fibers are not only easier to fabricate and maybe better for short distance/lower bandwidth applications where ease of handling and cost are drivers. Single-mode (SM) optical fibers generally possess a smaller core and lower numerical aperture (NA) than do MM fibers such that only the lowest-order mode propagates and no modal dispersion is present. Single-mode fibers are required for high-capacity communications over longer distances. Graded-index (GI) fibers are MM waveguides where the refractive index across the core is graded in a nearly parabolic manner, which balances the time for a given mode to propagate a certain direction. As a result, modal dispersion is significantly reduced [5, 11].

2.2.2 Double-Clad Optical Fiber

Optical fibers whose core has been doped with light-emissive species can be used as an optical amplifier or laser. The details and uses of these fibers are provided in Sections 2.1.2 (Active Optical Properties) and 5 (Applications), respectively, and so will not be described at length here. Suffice it to say that the excitation of the active species requires an optical pump; efficiently collecting the pump light into the fiber core can be problematic given the core's often small size. One approach to lessen this difficulty is to pump the larger cladding, rather than the core directly. In order to do this effectively, the cladding must itself act as a waveguide: a secondary cladding of lower-refractive index surrounding the higher refractive index active core is then necessary. This "double-clad" design is particularly useful in high-power (>1 kW) fiber-based laser designs where significant pump powers are required to achieve the desired laser output power. Additionally, double-clad fibers permit the use of lower-brightness diode sources for efficient pumping of the active core through brightness conversion of light in the cladding. The cross section of this pump cladding often is shaped, such as with a flat edge or hexagonal symmetry, in order to break the circular symmetry and facilitate intersection of the helical cladding modes of the pump with the active core. This design provides a means both of efficient pumping and excitation. References [9] and [5] provide excellent additional details on double-clad designs and uses.

2.2.3 Microstructured and Photonic Crystal Optical Fiber

MOFs and photonic crystal fibers (PCFs) constitute classes of optical fibers where the cross-sectional geometry is periodically modified in order to control the propagation characteristics of the light [12]. These periodicities in the material, whose length scales generally are commensurate with the wavelength of light, beget periodicities in the refractive index profile that create Bragg-like conditions for allowed and forbidden propagation energies and directions associated with the transverse components of the electromagnetic modes. For completeness, it is noted that some dispersion shifted/flattened (telecommunications) fibers have index structures that can be several times larger than the wavelength. A representative image of a PCF cross section is provided in Figure 4. Though MOFs and PCFs have been fabricated from a wide variety of glasses, the majority of structures are based on silica given its high strength, low loss, and commercial availability. The ability to use both silica and the fiber's geometric structure to realize properties that a conventional silica fiber would not otherwise possess has opened many doors to important applications, such as sensing, low-latency communications, and supercontinuum (SC) generation. As the

creation of a continuous and broad spectra, SC generation arises when short, high-power laser pulses propagate through a nonlinear media (here the fiber). Such spectral broadening can rely on a variety of nonlinear effects, including SPM, FWM, soliton fission, and Raman scattering. While SC generation can be observed in many nonlinear media, MOFs and PCFs are particularly useful because they can provide for small mode sizes and tailored dispersions that facilitate enhanced nonlinearities [13].

3 Optical Fiber Glasses

3.1 Silica and Silicates

As specifically relates to optical fiber, silica has always been the main glass former used in all practical and large commercial scales. This is due to the purity and vapor-phase processability of the precursor SiCl_4 . Both as a glass and as an optical fiber, SiO_2 can be produced with nearly intrinsic properties, of which the most important are transparency and strength.

Within the spectral region of low intrinsic loss, silica exhibits a minimum transmission of about 0.2 dB/km at a wavelength of 1.55 μm . The V-curve for silica was provided in Figure 2. Silica glass is the only material for which the theoretical transmission and that measured in practice coincide, again a testimony of testament to the degree of engineering and optimization of the CVD processes employed in the manufacturing of silica optical fiber. For all intents and purposes, impurities have been removed from the process, though, in some cases, such as for non-commodity (i.e. specialty) designs and compositions, some impurities can still be present. Near the low-loss wavelengths in silica, transition metals, rare earths, and hydroxyl groups (OH) can limit transparency. It is worth noting that high OH concentrations in SiO_2 glass do improve its ultraviolet (UV) transmission, so that optical fibers for application in the UV spectral range do typically have OH purposely included.

When properly drawn and coated, silica-glass optical fibers can also exhibit nearly theoretical tensile fracture strength, in excess of 3 GPa. This is due in part to the high draw temperature, which can anneal away any cracks or scratches on the glass surface. The high strength of SiO_2 glass correlates with its refractory thermal nature (both originating from the strength of the Si–O bond) and its relatively high chemical inertness and high laser damage threshold. Not surprisingly, the centrality of silica glass to all optical fiber applications of commercial consequence stems from this remarkable combination of properties; see Table 1.

A variety of oxides generally are added to silica to modify its refractive index, thermal expansion coefficients, and viscosity as a function of temperature. The most

Source: After [14].

common are GeO₂ (germanosilicates), Al₂O₃ (aluminosilicates), P₂O₅ (phosphosilicates), F (fluorinated silicates), and B₂O₃ (borosilicates). When added to SiO₂, GeO₂ increases the refractive index and enhances photosensitivity, P₂O₅ increases the refractive index and reduces glass viscosity, Al₂O₃ increases the refractive index and enhances the solubility of rare earth dopants, B₂O₃ reduces the refractive index and increases the coefficient of thermal expansion, and F reduces the refractive index and the glass viscosity.

Doping with laser-active species, most notably the rare earths, is employed for the realization of optical-fiber amplifiers and lasers. In the case of active optical fibers based on silica, a dopant is often required to lessen phase separation of the glass and the resulting clustering of the rare earth oxide (RE₂O₃) since the RE₂O₃–SiO₂ systems display considerable immiscibilities [15]. Alumina (Al₂O₃) is the most common additive to silica though phosphorus pentoxide (P₂O₅) also can be used. Greater detail on silica and silicate-based optical fibers can be found in [11, 15] as well as in references therein.

3.2 Phosphates

Phosphates constitute a family of oxide glasses where the principal glass-forming species is phosphorus pentoxide, P₂O₅ (Chapter 7.9). The structure of phosphate glasses is based on PO₄²⁻ tetrahedra whose P=O double bond is credited for the reduced thermal and mechanical properties of phosphate glasses in comparison with silicates. Although P₂O₅ is considered a glass former, phosphate glasses are always multicomponent with a wide range of possible network intermediates and modifiers. Of particular note are the alkaline earth oxides (i.e. MgO, CaO, SrO, and BaO), alkali oxides (i.e. Li₂O, Na₂O, K₂O), and sesquioxides (e.g. Al₂O₃ and B₂O₃). Each contributes in

different ways to increase chemical durability and decrease the phosphate glass solubility in water and tendency to devitrify. Given the broad range of phosphate glass compositions, it is difficult to define specific draw temperatures or optical and thermal property values. Suffice it to say that phosphates are considered soft glasses; they definitely have reduced mechanical strength relative to silica and typically draw into fiber at temperatures of the order of 800°C. Attenuation values from fibers reported in the literature range from about 0.1 to several dB/m in the near IR spectral range; see Table 1.

Phosphate glass optical fibers are used most notably for fiber lasers and amplifiers with high gain per unit length. As already noted, the impact of optical nonlinearities scale with distance and so shorter amplifiers and lasers imply a reduced buildup of parasitic effects as well as reduced device dimensions. Phosphates can incorporate a higher rare earth concentration prior to the onset of concentration quenching than can conventional silicate glasses. Phosphates can, for instance, accommodate rare earth (e.g. Yb³⁺) doping concentrations higher than silica by about one order of magnitude.

3.3 Infrared Glasses

3.3.1 General Remarks

Infrared glasses are generally defined as transmitting light at wavelengths beyond the transparency range of conventional silica-based glasses and fibers. This includes the mid-infrared spectral region, from about 2–5 μm wavelengths, and the far infrared, which ranges from about 8–12 μm wavelengths and possibly longer. Interest in these spectral regions stems from the fact that these are associated with the sensing of biological and chemical species (~ 3 –12 μm range), thermal signature identification and countermeasures (~ 8 –12 μm range),

astronomy/cosmology ($\sim 8\text{--}12\ \mu\text{m}$ range), and weather forecasting ($\sim 3\text{--}5$ and $8\text{--}12\ \mu\text{m}$ range).

In general, infrared glasses are characterized by constituents that are heavier in molar weight and/or weaker in bond strength than conventional silicates. The combination of heavier structural species and weaker bonds serves to shift to longer wavelengths the multiphonon vibrational absorption bands. Since the region of lowest intrinsic loss for a glass is near the wavelength where the edge of these absorption band intersects the attenuation associated with Rayleigh scattering, this redshift in the molecular absorption band yields an intrinsically lower-loss optical fiber. Lower-loss optical fibers are of great interest for long-haul communications and high-energy lasers. Additionally, the reduced vibrational energy also implies a lower non-radiative (multiphonon) relaxation rate for active light-emissive dopants in these glasses. As a result, light emission from infrared glasses is intrinsically more efficient than in higher phonon energy silicates.

A thorough treatise on infrared optical fibers, the glasses from which they are made, how they are fabricated, their properties and applications is given in [14] and in Chapter 6.5. Accordingly, only a brief description of these important glass families is provided here. Table 1 provides a comparison of properties for selected oxide and non-oxide infrared glasses.

3.3.2 Heavy Metal Oxides

Heavy metal oxide (HMO) glasses fill a somewhat unique niche in optical-fiber glasses because they are *oxides*, thus exhibiting some of the beneficial properties of silicates, such as relatively high strength and thermal stability while being composed of heavier species and so possessing extended transparency into the infrared. The two systems most commonly studied and fabricated into optical fibers are the tellurites and germanates.

Tellurite glasses are based on TeO_2 . They were first studied in 1952 and then considered for optical fiber only in 1994. Relative to silica and to other infrared glasses, tellurites enjoy a wide transmission window that extends from the UV to the mid-IR ($\sim 0.35\text{--}5\ \mu\text{m}$) and have glass and chemical stability appropriate for many applications, high linear and nonlinear refractive indices, and relatively low phonon energy ($\sim 600\text{--}800\ \text{cm}^{-1}$ for tellurites versus $1100\ \text{cm}^{-1}$ for SiO_2). They are, however, less thermally stable with glass transition temperatures of only about $300\text{--}350\ ^\circ\text{C}$.

For optical fibers, the best-studied tellurites are related to the $\text{TeO}_2\text{--ZnO--Na}_2\text{O}$ system, common dopants further including La_2O_3 and WO_3 . Tellurites, which generally are made via a melt/quench method, often possess hydroxyl (OH) impurities that limit transparency unless dehydration methods are employed not only for their precursors but also during the melting process. The lowest

tellurite fiber attenuation values achieved to date are about $0.5\ \text{dB/m}$ at a wavelength of $2.1\ \mu\text{m}$ [14].

Another important HMO glass family is germanate glasses whose structures are analogous to those of silicates because GeO_2 is isostructural with SiO_2 . Since GeO_2 is heavier than SiO_2 , however, germanates transmit further into the infrared and have similar intrinsic losses as SiO_2 (though IR absorption is redshifted, Rayleigh scattering would be higher due to the higher refractive index) but are less thermally stable than silica. The glass transition temperature and melting point for GeO_2 are about $700\ ^\circ\text{C}$ and $1115\ ^\circ\text{C}$, respectively, whereas for SiO_2 these values are ~ 1400 and $1726\ ^\circ\text{C}$.

Germanate glasses often are multicomponent. They are typically realized through a melt/quench process. Even though GeO_2 regularly is doped into silica with one of the CVD processes, the direct formation of GeO_2 core optical fibers is made difficult by significant mismatches in thermal expansion. That said, silica-clad optical fibers possessing very high GeO_2 core concentrations and losses of only about $20\ \text{dB/km}$ at $1.9\ \mu\text{m}$ have been realized [16].

Of the main oxides used for optical fiber (SiO_2 , GeO_2 , P_2O_5 , and B_2O_3), GeO_2 has the highest (linear) refractive index, nonlinear refractive index (n_2), peak Raman scattering cross section, and photorefractive effect. The large n_2 value, approximately three times higher than in SiO_2 , suggests germanate glass optical fibers for four-wave frequency conversion devices. The high Raman gain of GeO_2 , approximately 10 times larger than for SiO_2 , marks these glasses as useful for efficient fiber-based tunable Raman fiber lasers and amplifiers. Lastly, the strong photosensitivity of GeO_2 , both when doped into SiO_2 and as a germanate glass, suggests the ability to write Bragg gratings into the fiber at lower UV fluence levels and without hydrogen loading as is often done for silica fibers.

Some useful compositional, physical, and optical properties of the more common tellurite and germanate glass optical fibers are provided in [14].

3.3.3 Fluorides

Fluoride glasses were discovered accidentally in the early 1970s through attempts to grow fluoride laser crystals. The ionicity of the fluoride bond makes fluorides nontraditional glass-forming systems relative to oxides and chalcogenides (Chapter 6.5). The melts generally exhibit low viscosities, and glass formation largely is based on the “confusion principle” whereby the presence of multiple components make it difficult for a crystal to form upon cooling of the melt. Relative to other infrared glasses, fluorides generally exhibit the lowest refractive index and optical nonlinearity, which makes them of value for high-power laser applications.

The first fluoride glasses were based on ZrF_4 as the main constituent. To date, the most common and

well-studied fluoride glass is “ZBLAN” (Chapter 6.5) whose base molar composition is about $53 \text{ ZrF}_4 - 20 \text{ BaF}_2 - 4 \text{ LaF}_3 - 3 \text{ AlF}_3 - 20 \text{ NaF}$. In addition to the fluorozirconate glasses, others of interest include fluoroaluminate glasses, based on aluminum fluoride, and fluorindate glasses, based on indium fluoride. The fluoroaluminates and fluorindates generally possess better chemical stability than do fluorozirconates. Mixed anion systems, such as the fluorophosphate and oxyfluoride glasses, have also been developed.

As noted, relative to silicates, infrared glasses generally possess weaker bonding, which also means reduced thermal and mechanical properties. For example, the glass transition and fiber draw temperatures for ZBLAN optical fiber are about 260 and 310 °C, respectively, whereas recent strength values of 700 MPa for 125- μm fibers have been realized. For telecommunication-grade silica optical fiber, these values are about 1100 °C (T_g), 2000 °C (T_{draw}), and > 3 GPa.

The weak bonding is useful for intrinsically low-loss and higher-efficiency lasing; however extrinsic factors have always plagued the transmission of fluoride optical fibers. In theory, ZBLAN should exhibit a minimum loss of $\sim 0.01 \text{ dB/km}$ at a wavelength of 2.5 μm , which is approximately 20 times lower than that of silica (0.2 dB/km at 1.5 μm). Whereas the record low loss to date is $\sim 0.4 \text{ dB/km}$ at 2.35 μm , typical background loss of commercial fluoride fibers is $\sim 150 \text{ dB/km}$ for ZrF_4 -based glass fibers (wavelength range of 2.3–3.6 μm) and $\leq 450 \text{ dB/km}$ for InF_3 -based glass fibers (wavelength range of 3.2–4.6 μm). Only silica-based glasses are reliably manufactured with the CVD process; all other glasses being made by a melt/quench method, which leads to added impurities. In the case of the fluorides, these higher losses are associated with transition metal, rare earth, and OH impurities as well as extrinsic scattering from occasional bubbles, crystallites, and inclusions.

That said, even with present loss values, the reduced phonon energies (600 cm^{-1} for ZBLAN versus 1100 cm^{-1} for silica) associated with the weak bonding have permitted a wide range of novel fluoride glass fiber lasers at wavelengths not possible with silicates. Of particular note are numerous fluoride glass fiber lasers doped with rare earths based on upconversion of near-infrared pumps to visible and UV wavelengths [7] and also the praseodymium-doped fluoride fiber that amplifies communication signals at the 1.3 μm zero dispersion wavelength.

For completeness it is worth noting that fluorides are part of the broader halide family of non-oxide glasses (Chapter 6.5). Generally speaking, fluorides are more stable and possess a greater glass-forming range than do glasses based on other halide glass formers such as ZnCl_2 .

3.3.4 Chalcogenides

Chalcogenide glasses derive their name from the chalcogen elements from which they are formed, namely, sulfur (S), selenium (Se), and tellurium (Te); see Chapter 6.5. The glass-forming ability of this glass family tends to decrease with increasing molecular weight; i.e. it decreases in the order sulfides, selenides, and tellurides (which are based on elemental Te and thus not to be confused with the TeO_2 -based tellurites already described). The best-studied and commonly employed systems are in the binary systems of As with S, Se, and Ge and in the ternary systems of As–Se with Ge and Te, as well as in the Ge–As–Te, Ge–Sb–Se, and Ga–La–S families. The glass transition and fiber-draw temperatures range from 350 to 550 °C and from 400 to 700 °C, respectively.

From the perspective of optical fiber, chalcogenides are of greatest interest for mid- and long-wave IR light propagation. The relative heaviness of the constituent elements coupled with weaker bond strengths shifts the infrared absorption out to quite long wavelengths, in some cases in excess of 20 μm . This makes such fibers of value for astronomical observations and imaging where no other glasses or fibers transmit. In addition to this extended transparency in the infrared, chalcogenides have the highest nonlinear refractive indices (n_2) among optical glasses, making them of interest for low-power fibers in nonlinear optical devices.

The minimum intrinsic loss of chalcogenide optical fiber is near or slightly below that of silica, though at longer wavelengths, e.g. $\sim 0.01 \text{ dB/m}$ at 5.0 μm for As_2S_3 . In practice, however, losses generally are considerably higher because of impurities from the melting process as well as glass and homopolar bond defects. More typical mid-infrared attenuation values are in the range of 0.1–10 dB/m. To date, the lowest loss observed in a chalcogenide is 0.012 dB/m at 3.0 μm from a multimode As_2S_3 optical fiber.

4 Optical Fiber Fabrication

The fabrication of optical fiber requires specific materials possessing the requisite optical, physical, chemical, and thermal properties for a given fiber design, which can, in addition, be converted from either the melt or a glass “preform” or “blank” into the resultant fiber. This section describes the basics of these two considerations.

4.1 Glass Formation

There are many ways in which to make a glass. For the purposes of this Chapter, only those that are used in

Figure 5 Sketch of the chemical vapor deposition process (a) modified chemical vapor deposition (MCVD), (b) plasma-enhanced chemical vapor deposition (PECVD), (c) outside vapor deposition (OVD), and (d) vapor axial deposition (VAD). Source: After [5].

reasonable scale to make glasses relevant to optical fiber are noted. Thorough reviews of conventional optical fiber fabrication are given in [11] and [5] and of photonic crystal fibers are given in [5]. Representative schematics for the CVD processes as well as the fiber-draw approach to fiber formation are provided in Figures 5 and 6.

4.1.1 Melt/Quench

Rods and tubes can be extracted from melt-quenched glass, typically via milling and polishing, from which a

core/clad preform can itself be constructed based on the optical fiber design. Judicious selection of the starting materials that are batched and melted in an appropriate crucible is critical to obtaining the requisite refractive index, thermal expansion coefficient, and viscosity–temperature relationships, among other important properties. Depending on the chemistry of the melt, and particularly on the vapor pressure of its constituents, additional conditions may be necessary such as a controlled, low-oxygen content atmosphere as in the case of fluoride glasses or sealed ampoules for the melting

Figure 6 Sketch of the fiber-draw process. *Source:* After [5].

of high-quality and high-purity chalcogenide glasses. Contamination caused by dissolution of the crucible into the glass melt and by impurities resident in the precursor batch compounds can yield extrinsic absorptions and modify the physical and chemical properties that limit the performance of the subsequent glass. Additionally, contamination of the glass from atmospheric moisture can be problematic since OH species strongly absorb at many wavelengths of practical interest. Care must be given in all instances to make the melt, hence resultant glass, as free of impurities, bubbles, and chemical heterogeneities as possible for optimal fiber formation and optical performance.

4.1.2 Chemical Vapor Deposition

All silica-based optical fiber of commercial consequence is drawn from glass fabricated using chemical vapor deposition methods, namely, outside vapor deposition (OVD), modified chemical vapor deposition (MCVD), vapor axial deposition (VAD), or plasma-enhanced chemical vapor deposition (PECVD). Representative schematics are provided in Figure 5 for these processes

whose applications to the fabrication of optical fiber is thoroughly described in [5, 11].

In all cases, the base reaction is $\text{SiCl}_4 + \text{O}_2 \rightarrow \text{SiO}_2 + 2\text{Cl}_2$. Though the processing specifics differ, the enabling chemistry is similar; i.e. the high temperature oxidation, thermophoretic deposition of glass particulate soot, and subsequent sintering and consolidation of glass soot derived from volatile halide species. The exact temperatures and times required for each of these steps differ, depending on the processing method, the size and design of the preform, and the compositions of the glasses.

In addition to yielding a final glass rod that contains both core and clad region in their desired proportions, the particular power of these CVD approaches is that SiCl_4 possesses a vapor pressure that is nearly 10^{12} times higher than those of the most detrimental impurities to optical performance, transition metals phases such as Fe_2Cl_6 . Hence, CVD-derived silica-based optical fibers can exhibit intrinsically low attenuation values.

In order to obtain silicate optical fibers, the GeO_2 , P_2O_5 , B_2O_3 , and/or F additives to the SiO_2 are formed through vapor-phase reactions from their respective volatile halides: GeCl_4 , POCl_3 , BCl_3 , and/or SiF_4 . Either because BCl_3 (or BBr_3) and SiF_4 are gases or because the GeCl_4 and POCl_3 precursor liquids have a suitably high vapor pressures, in both cases the doping chemical can be added directly into the SiCl_4 gas stream. As done for doping with Al_2O_3 or light-emissive rare earth species [5, 11], one can adjust further the glass composition by doping the deposited soot via solutions with dissolved salts (e.g. AlCl_3 , YbCl_3 , and ErCl_3). A complete solid solution exists between SiO_2 and GeO_2 and P_2O_5 such that glass stability is not problematic, though some volatility of the GeO_2 and P_2O_5 can occur at the high temperatures required for preform consolidation and collapse. This volatility can lead to undesirable changes in the refractive index profile of the resultant preform, which in turn influences the performance of the resultant optical fiber. Other dopants, such as Al_2O_3 , B_2O_3 , and the lanthanide oxides (e.g. Yb_2O_3), do possess compositional regions of liquid-liquid immiscibility or a tendency to crystallize. Accordingly, more limited ranges exist for their addition into SiO_2 though novel methods for obviating these traditional issues have been developed [15].

4.2 Fiber Formation

As with glass formation, there are many ways to make a fiber. Whereas many polymer fibers, and indeed some non-optical glass fibers, are fabricated by extrusion, optical fibers are not because of the critical need for a pristine surface from which the strength of the resultant fiber is largely determined (see Chapter 3.12). Glass optical fibers are either formed directly from the melt in some specialty

cases or, more conventionally, drawn from a (core/clad) glass rod directly into fiber. These processes are described in more detail below.

4.2.1 Double Crucible

Glasses such as selected chalcogenides are not sufficiently stable to yield a bulk rod. They can be formed into fibers instead by melting of the components followed by controlled flow of this melt out of an orifice at the bottom of the melter. In order to achieve a core/clad geometry, one melt stream (generally that of the core) is initiated, and a second melt stream (generally that of the cladding) is then flowed around it; these melt streams originated from concentric melters, each controlled to melt uniformly, homogenize the core or clad glass, and yield a stream with proper melt viscosity such that limited interactions between core and clad result upon fiber formation.

4.2.2 Fiber Draw

The draw process is vastly dominant to fabricate optical fibers. It is distinct from extrusion, spinning, or pultrusion in that a nozzle or die is not employed. These processes are applicable to polymer fibers (optical and non-optical) as well as non-optical glass fibers such as those used for thermal insulation or acoustic isolation (Chapter 9.3). Because fiber strength is of paramount importance, particularly in telecommunication applications, the surface of the (typically silica) optical fiber cannot be contacted, obviating the use of a die or spinneret through which the fiber is formed.

Whereas the fiber is formed directly from the melt in the double-crucible method, the fiber-draw process begins with a glass rod (also called a preform or blank) that contains the core and clad glasses. The subsequent reduction from preform to fiber generally is an affine transformation whereby the diametric ratio of core and clad remains constant. If pressure or vacuum is employed during the draw, as is occasionally done in the fabrication of photonic crystal fibers, then the geometric ratios between preform and resultant fiber are not necessarily constant, and pressure is another processing parameter in the ultimate fiber design and performance.

In general, glass optical fibers are formed with a vertical draw tower. The glass preform is held at the top of the tower in a down-feed unit that controllably lowers it into a furnace. Under certain circumstances, the preform can be rotated during the draw to facilitate greater uniformity of cross-sectional core diameter or to induce helical perturbations along the fiber's length. The furnace design, often including inert atmosphere control, depends on the glass from which the fiber is made. The temperature of the furnace usually is best determined from the tension of the fiber during the draw, which is important for

maintaining good diameter control: a temperature appropriate in this respect is typically that at which the viscosity is about 10^6 poise (10^5 Pa·s). For conventional silica optical fibers, these temperatures are between about 1925 and 2000 °C. For softer glasses that are either prone to crystallization or have steeper viscosity–temperature relationships, the working range can be markedly shorter ($\Delta T \sim 10\text{--}20$ K).

During the beginning of the fiber-draw process, the temperature usually is raised above the eventual draw temperature in order to hasten the softening of the glass preform and its localized flow into a “drop” or “gob” that ultimately exits the furnace and defines the transition from bulk preform into fiber. This transition section is also known as the “neck” or “neck-down” region. The fiber is then pulled down the tower through a series of other instruments such as those that measure the bare (core/clad) glass fiber diameter, apply and cure polymer coatings (more detail below), display the concentricity of the coating around the glass fiber, measure the final coated fiber diameter, provide the tension for pulling the fiber from the locally softened preform (which is slowly lowered into the furnace), and ultimately collect the fiber on a spool for subsequent use.

Upon sufficient cooling of the fiber, though still on-line prior to collection, one or often two polymer coatings are applied. In most cases, they provide protection of the underlying glass from the strains and abrasions of installation and use (Chapter 3.12). The first polymer layer, called the primary coating, is relatively soft and is intended to relieve the strain placed on the fiber during use so that the loss of light caused by micro-bending can be lessened. The second polymer layer, called the secondary coating, is generally hard and provides abrasion resistance. The coatings are applied in oligomeric form to the glass fiber on-line during the draw by a series of dies that do not contact the glass surface but do provide a thin separation for the coating to wet the glass with well-defined thickness. The coatings are then cured on-line with an ultraviolet lamp. Whether the primary is cured first or both primary and secondary coatings are cured simultaneously (called wet-on-wet coating) depends on the application, hence volume of fiber and draw speed. For more specialty uses, a single coating may be sufficient. One variation on this theme includes polymer clad silica (PCS) where the fiber is only composed of silica with no core/clad structure and the single (hard) polymer coating constitutes the cladding. A second variation is double-clad fibers used in fiber laser designs, where the fiber is constructed with an active glass core, passive glass clad, and a low-refractive index polymer cladding that provides light guidance for the laser pump light in the glass cladding. A protective outer polymer coating often is used in double-clad fiber designs.

For completeness, the aforementioned microstructured and photonic crystal optical fibers generally are formed via fiber-draw processes as well. However, the preforms from which the fibers are drawn typically are ensembles of stacked rods or tubes of requisite periodic structure. Although tedious, this “stack and draw” method does enable very sophisticated and multi-material structures to be fabricated and drawn into fiber.

5 Applications

In 2013, the National Research Council of the United States National Academies published an updated report on the state of optics and photonics [17] whose annual global economic impact was estimated at \$7.5 trillion. Optical fiber is a subset of this field, which was fully expected to continue to grow because of their many direct or indirect applications. The principal application areas are (i) communications, information processing, and data storage; (ii) defense and national security; (iii) energy; (iv) health and medicine; and (v) advanced manufacturing. It is beyond the scope of this chapter to delve deeply into each though a brief description is provided below. For more detail, the reader is referred to the report itself [17].

Much of the initial impetus behind the development of optical fibers stemmed from their potential use in communications. It can be argued that of all the applications of glass optical fibers, those for global communications remain not only the largest in scale but also the most enabling since such fibers have brought knowledge and given voice to people around the world who previously had no access to information or means for commerce. Around the turn of the twenty-first century, a meaningful transition occurred when Internet traffic associated with data surpassed that for voice-based telephony. People speaking with people approximately scales with population, which grows at a rate of only about 1% per year. Computers talking to computers do not, so very rapid increases in Internet traffic spurred a growth in the demand for glass optical fiber that continues to this day. The Internet of Things, continued growth in social media, cloud computing, and data storage will only increase this demand in the future.

There have always been defense and security applications for optical fiber, and indeed, the Internet evolved from the US Department of Defense’s Advanced Research Projects Agency Network (ARPANet). The dielectric nature of glass obviates many electronic means of tapping into signals, making optical communications more secure. More recently, the use of lasers for projecting nearly instantaneous power at long distances without having to risk harm to individuals has ushered in

significant growth in high-energy lasers. Though free-electron, chemical, and solid-state lasers are all of interest, high-energy lasers based on glass optical fibers have enjoyed considerable attention because they can be small, light, fully integrated, and meet many of the requisite power needs [9].

The main use at present of optical fiber as relates to energy is for the monitoring of oil and gas wells. In particular, glass optical fibers are employed in distributed temperature and acoustic sensor systems, which can allow for increased production and reduced risks. The high pressures, temperatures, and chemically aggressive environments have all but limited the choice of optical fibers to those made from either silica or, in some cases, pure silica cores with lower-index fluorinated silica cladding, which resist hydrogen degradation better than other glass families. There have been recent successes in using high-power lasers for actual drilling, which could greatly speed the exploration of new wells.

Photonics plays an ever expanding role in health and medicine where the intrinsically small dimensions and flexibility of glass fibers are most valuable advantages. Applications include fiber bundle endoscopes for imaging within the body, fibers as light pipes to induce localized chemical reactions associated with photodynamic therapies, and more recently, though yet immature, optogenetics whose goal is to control and record neuron activity in living organisms. Infrared optical fibers – particularly fluoride glass optical fibers – are used to transmit mid-infrared light such as that at 2.8 μm from an Er : YAG laser for use in ophthalmology and dentistry.

Advanced manufacturing has grown markedly over the past decade as modern conveniences continue to shrink in dimensions and increasingly complicated shapes are more rapidly fabricated. While lasers in general play enabling roles, the specific use of glass optical fiber is more limited but growing as with some of the other applications noted above. The use of fiber in advanced manufacturing, at present, largely relates to its flexibility such that laser light can be brought from the source to the part being fabricated without complex bulk optical elements where misalignment can occur in articulated robotic systems. A second and growing area for glass optical fiber in manufacturing relates to fiber-based high-power lasers where the quality of the laser beam can be considerably higher than in bulk solid-state laser systems.

6 Perspectives

To say that optical fiber is central to modern life is an understatement. The ubiquity and instantaneous availability of information, as just one example, is entirely

enabled by optical fibers in both passive and active forms. While silica will remain the material of choice, continued advances in infrared glasses, most likely fluorides, will open doors to new applications [5]. Ever greater control of the properties of light will be engineered into the fibers through judicious and clever combinations of geometric structuring and materials selection [8]. In addition to expanded roles in present technologies such as communications, defense, medicine, and manufacturing, applications where fibers play more enabling roles will grow and include energy independence, advanced genomics (e.g. optogenetics), autonomous vehicles, and space exploration. Only time will tell what the future holds, but there is no question that the future for glass optical fiber remains very bright!

Fluoride and Chalcogenide Glasses for Mid-infrared Optics

Bruno Bureau and Jacques Lucas

Verres et Céramiques, Institut des Sciences Chimiques de Rennes UMR-CNRS 6226, Rennes, France

1 Introduction

The glass world has long been dominated by oxides because of the exceptional ability of SiO_2 , B_2O_3 , and P_2O_5 to form strongly associated melts. In the last past decades, however, new glasses have been formed from metallic salts such as fluorides and chalcogenides whose unusual properties, primarily optical, have led to important practical applications. Research and development in this field has in fact been boosted by the need for light-transmitting materials in the infrared (IR) region. In contrast to oxides glasses, whose opacity beyond $3\text{ }\mu\text{m}$ make them inappropriate for mid-IR technologies, fluoride and chalcogenide glasses are low-phonon materials because the vibrational modes of their glass framework shift the IR cutoff to a maximum of about $20\text{ }\mu\text{m}$. This is why chalcogenides [1–3] and fluorides [4, 5] have found many applications, ranging from IR lenses as key components in thermal-imaging and night-vision systems to optical-waveguide fibers transmitting IR light in energy transfer or remote analytical devices.

This chapter will focus on those glasses for which applications have been found, thus excluding a number of halides (chloride, bromide, and iodine) and chalcogenides that suffer from a poor chemical durability, especially under humid conditions, or from weak mechanical properties and resistance to crystallization. The first series of materials selected encompasses complex ZrF_4 -based glasses known as ZBLAN, because they are a mix of Zr, Ba, La, Al, and Na fluorides, as well as metal trifluorides such as InF_3 , GaF_3 , or AlF_3 [5]. The second group to be discussed deals with composition ranges where viscous liquid may be formed from chalcogens ($\text{X} = \text{S}, \text{Se}, \text{Te}$). This group also

includes glasses made from chalcogenides such as As_2X_3 , Sb_2X_3 , GeX_2 , and Ga_2X_3 [1, 6, 7]. After having briefly reviewed the issue of glass transparency, we will describe vitrification in these systems, then glass structure, and finally the main current uses of these materials in optics. For detailed information on important topics directly relevant to the present theme, we will refer to other chapters on floppy–rigid structural transitions (Chapter 2.7), luminescence (Chapter 6.3), silica optical fibers (Chapter 6.4), and glass ceramization (Chapter 7.11).

2 Glass Transparency in the Infrared Region

At short wavelengths the optical transparency of a material is limited by the interaction of light with the electrons involved in chemical bonding. At high wavelengths, optical losses originate in absorption by the vibrating atoms, which form dipoles coupling with the oscillating electric field of light. As indicated by the simple model of the harmonic oscillator, the frequencies at which light begins to couple with network vibrations decrease with increasing atomic masses and decreasing bond strengths. In silicate glasses, the absorption rises to 50%, at about $3\text{ }\mu\text{m}$ in the near-IR (Figure 1). Hence, the most efficient strategy to expand the spectral window of glasses is to deal with atoms heavier than oxygen or silicon to lower phonon energy and shift the multiphonon cutoff to longer wavelengths. With fluorine, sulfur, selenium, and tellurium, the optical transparency indeed extends further and further in the mid-IR and even in the far-IR with the heaviness of the glass former (Figure 1).

In practice, the reasons for developing glasses transmitting light in the mid-IR region are several. First, blackbody emission shifts toward the IR with decreasing temperatures. Whereas the sun, with a corona temperature of

Figure 1 Influence of atomic weight and bond strength on the infrared transparency of glass families.

Figure 2 Shift to lower wavelengths and intensity increase with temperature of blackbody radiation. Emission by the human body in the mid-infrared near 10 μm .

about 6000 K, emits most of its energy in the visible region, the radiation emitted at room temperature – for instance, by the human body – peaks near 10 μm (Figure 2). Optics operating in this region are thus necessary for thermal imaging in night-vision systems and, more generally, for all kinds of IR camera and IR transmitting optics. Second, although generally transparent in the visible region, the atmosphere exhibits two windows where light is strongly absorbed. One is the 3–5 μm region just in between the wavelength of the O–H elongation vibration and the strong bending mode of the H_2O molecule. Extending from 8 μm , after water absorption, to about 13 μm where CO_2 molecules begin to absorb, the second window has a greater width that makes it well suited to visualize thermal objects at room temperature such as human or animal beings. Third, as already noted, the IR region is the domain of molecular vibrations. Hence, every kind of molecules has a spectral fingerprint, which is roughly located

between 2 and 12 μm , so that chemical species can be detected and analyzed from IR spectra.

For all applications, however, an important feature to be accounted for is Fresnel loss, which is caused by photon reflections at the glass surface and is proportional to the refractive index n of the material. This parameter depends on the polarization of the atoms forming the glass. It is strongly enhanced by heavy elements, so it increases from 1.5 for silicate or fluoride glasses to 2–2.5 for selenides and even to 3.2 for tellurides. As a result, reflection losses increase sympathetically from about 15 to 50%, respectively (Figure 1), which implies that the surface of chalcogenide glass lenses needs to be coated with antireflective films.

Finally, a few words are probably useful to justify why these materials cannot generally be used in the visible range. At short wavelengths (Figure 1), optical absorption is due to electronic transitions associated with both bonding and nonbonding electrons. The latter gives rise to the so-called band-gap absorption, whose cutoff wavelength is $\lambda_c = hc/E_g$ for a glass with a band gap E_g . The glass is transparent at wavelengths $\lambda > \lambda_c$ where light is not sufficiently energetic to induce an electronic transition. Conversely, the material is opaque at wavelengths $\lambda < \lambda_c$ where light is absorbed to promote an electronic transition. Because of band-gap absorption, a bulk glass thus filters out all visible light of wavelengths shorter than λ_c and can then appear colored or even black.

Oxide glasses such as silicates are transparent in the visible because λ_c is located in the UV region at around 0.3 μm . The same applies to fluoride glasses. Chalcogenides, in contrast, markedly absorb in the visible because their band gaps are lowered by the lone pairs of nonbonding electrons sitting at intermediate levels between the valence and conduction bands. Chalcogen elements, moreover, are regarded as semiconductors because they lie in between metals and nonmetals in the periodic table, so electronic transitions become increasingly probable from sulfur to tellurium. In sulfide glasses, the transmission limit is

slightly displaced in the middle of the visible range, making these materials yellow or orange. For selenides, the color becomes dark red or black, and definitely black for tellurides, making these materials looking like an alloy rather than a glass. In summary, fluoride and chalcogenide glasses are unique for mid-IR technology, but useless for the visible and near-IR ranges where silicate glasses remain matchless.

3 Fluoride Glasses: Formation and Structure

3.1 Glass Formation in Metal Fluorides MF_x

Owing to the peculiar electronegativity of fluorine, fluorides can be roughly divided in two classes [5]. When the metal M has a high oxidation state, the formation of volatile molecular species is dominant, and the chemical bond is covalent. Typical examples are uranium hexafluoride, UF_6 , and silicon tetrafluoride, SiF_4 . If the metal is mono- or divalent (e.g. alkalis or alkaline earths), the material is highly crystalline with strong ionic bonds. This is the case of NaF or CaF_2 , which upon melting give rise to fluid, nonassociated liquids lacking any glass-forming ability.

Trivalent MF_3 or tetravalent MF_4 crystals (M = transition metal belonging to the 3d or 4d series in the periodic table) form giant 3-D frameworks based on the connection of octahedra or more complex corner-sharing polyhedra. The chemical bonds causing the formation of these networks are intermediate between covalent (overlapping of orbitals) and purely ionic as typically found in AlF_6 , GaF_6 , InF_6 , ZrF_7 , or ZrF_8 . The connection between those units can be very rigid without any possibility of varying the bond angle M–F–M. In this case, the solid and melt have similar short-range structures, so crystallization is the rule upon cooling. In some very special situations, however, a fluoride melt can be made up of diverse MF_x polyhedral units mutually connected between which bond angles are floppy and, thus, vary at little energy cost for the system. This situation leads to an associated melt showing a higher viscosity. Crystal formation then is thwarted by the existence of these nonperiodic polymeric networks, which persist when the melt is cooled down. As happening for silicate glasses, the viscosity of the metal fluoride polymer increases so much when the temperature drops that a glass forms when the viscosity reaches 10^{12} Pa s.

To prevent crystallization, an empirical rule is to use complex compositions in which competition between different possibly nucleating crystals is maximum (the so-called principle of confusion). In the 1980s, the activity in the field was strongly boosted by the search for

ultra-transparent glasses at telecom wavelengths. Many fluoride glass compositions were then discovered, but only a few were found suitable for applications. Since interest mainly lies in widening the transparency window toward the IR, only heavy metal fluoride glasses such as ZrF_4 and InF_3 are relevant.

In fluorozirconate glasses, the most popular composition is that of ZBLAN glass, namely (in mol%), 52 ZrF_4 ·19 BaF_2 ·5 LaF_3 ·4 AlF_3 ·20 NaF, where ZrF_4 , AlF_3 , and LaF_3 are considered as glass formers and the large ions Ba^{2+} and Na^+ as modifiers. Glasses based on InF_3 are also of interest since they are stable enough to be drawn into optical fibers. The phonon energy is lower for InF_3 than for ZrF_4 glasses so that the former transmit better in the IR thanks to a cutoff that is slightly shifted toward longer wavelengths, at 5.5 instead of 4.6 μm for optical fibers. In practice, the composition of these glasses is also complex with molar concentration of InF_3 close to 50% and various heavy metal fluorides (BaF_2 , PbF_2 , ZnF_2 , GaF_3 , or CdF_2) to keep the phonon energy as low as possible and to prevent crystallization from happening. Besides, small amounts of alkali chlorides can be also added to adjust the refractive index.

3.2 Polymeric Networks Based on ZrF_n Polyhedra

Determining the structure of fluoride and chalcogenide glasses becomes increasingly difficult when composition becomes complex, especially when major components have themselves a complex structural role. For fluorides, the most appropriate and simplest glass for structural investigation has the ratio $ZrF_4/BaF_2 = 2$. Because this glass is very unstable, fast quenching of the melt is necessary to obtain small flakes suitable for X-ray investigations. Thanks to its rather simple composition, this $BaZr_2F_{10}$ glass has also been investigated by computer simulation. Examination of the fluorozirconate crystal chemistry is also bringing important information about ZrF_x coordination polyhedra, where x varies from 6 to 8 with a most frequent value of 7. As a matter of fact, there exist a variety of polyhedral geometries around zirconium associated with a great flexibility of the Zr–F–Zr bond angle. Since fluoride glasses were discovered accidentally in a study of atomic substitutions in crystalline $LaZrF_7$, it is of interest to note that, according to X-ray investigations [8], ZrF_7 and LaF_8 polyhedra are connected to form a 3-D network in this rare earth fluorozirconate.

More generally, structural models have been established to integrate several sources of information (Figure 3). In X-ray diffraction studies, radial distribution functions (RDF) show Zr–Zr pair correlations indicative of short and longer Zr...Zr distances compatible with

Figure 3 Structure of ZrF_4 glass reticulated by ZrF_7 or ZrF_8 polyhedral units, with large ions such as Ba^{2+} acting as network modifiers.

ZrF_x polyhedra sharing edges and corners, respectively, the Ba^{2+} ions being a glass modifier. Interestingly, computer simulations lead to the same result with two clearly distinct $\text{Zr}\dots\text{Zr}$ distances. Another important point is to establish the role played by the lanthanide atom in ZBLAN glasses. The La content being small at around 4%, Nd^{3+} has been used as a dopant because rare earth spectroscopy with this ion as a probe is very sensitive to the local ligand field. The Nd^{3+} fluorescence spectra are very similar in the glass and parent crystalline LaZrF_7 , indicating that La^{3+} is incorporated in the glass network as LaF_8 polyhedra. Hence, there is a striking contrast with silicate glasses where Nd^{3+} absorption spectra are broad, indicating that this ion is instead a network modifier.

From these results, one concludes that these associated melts vitrify when their networks have a polymeric nature. The disordered polymer is made up of a variety of polyhedral connections, including small amounts of AlF_6 and LaF_8 in addition to the predominant ZrF_7 . Variations in bond angles then cause local disorder and a lack of periodicity, whereas the Na^+ and Ba^{2+} ions are glass modifiers. Both also contribute to foster the competition between crystalline phases that might precipitate, delaying in this way the devitrification process that remains here an issue.

4 Applications of Fluoride Glasses

4.1 General Considerations

Analyses by differential scanning calorimetry (DSC) are simple means to check that glasses have the required mechanical and thermal properties and also a strong enough resistance to devitrification [5–7]. For ZBLAN, a DSC analysis shows that its T_g is close to 260°C , i.e. well above the $120\text{--}130^\circ\text{C}$ required for practical applications, but also that crystallization is signaled by an exothermic peak at T_x of about 400°C . Hence, the glass must be fiberized between these two temperatures under severely controlled viscosity conditions such that the deformation rate is high enough but crystallization remains avoided. Besides, fluoride glasses are sensitive to thermal shock because of high thermal expansion coefficients ($17.2 \times 10^{-6} \text{ K}^{-1}$ for ZBLAN), which are consistent with their rather low T_g . Heavy metal fluoride glasses are stable under normal atmospheric conditions, but they are sensitive to moisture corrosion when temperature increases because the OH^- ion has the same size as F^- , so F/OH substitution at the glass surface is a ready source of corrosion.

4.2 Optical Fibers for Guiding Infrared Light

Fibers are by far the main commercial product for fluoride glasses [4, 9], in agreement with the fact that one of the main reasons for investigating them was the search for ultra-transparent materials. Although electronic absorption in the UV is not so different in fluorides compared with SiO_2 glass, the phonon absorption in contrast drastically shifts toward long wavelengths with phonon energies of 600 and 1100 cm^{-1} , respectively. Glass transparency is represented by V-shaped curves (Figure 4), indicating that the minimum optical loss is 0.2 and about 0.02 dB/km for SiO_2 and fluoride glasses, respectively. Because fluoride glasses have thus been considered as a substitute for silica in long-distance telecommunications, much effort has been paid to develop high-quality optical waveguides in single- or multimode configurations (i.e. depending on whether the core of the fiber is several or many times larger than the light wavelength, so single or many optical modes propagate). In both cases, however, a prerequisite for the internal reflections needed for light propagation is that the refractive index of the core be slightly higher than that of the clad glass. One thus needs to combine two glasses having similar properties, except for the refractive index. With the rod-in-tube method (Figure 5), the core glass is used for the rod and the clad glass for the tube: after strict adjustment of the rod into the tube, the preform obtained is drawn with a drawing tower and the fiber collected on a drum.

Figure 4 Comparison between the infrared transparencies of silica and fluoride fibers. Minima of the V-shaped curves of 1 dB/km for silica near the 1.55 μm telecom wavelength and of only 0.02 dB/km for fluoride at 2.9 μm .

Figure 5 Production of a single-mode preform (C) from two Se–Te vitreous alloys: one for the core rod (A) and the other for the cladding tube (B). A as a first step, the rod has to be drawn into a stick to get the requested final diameter ratio.

4.3 Passive Properties

In passive functions the fiber transmits the light from a source toward a target [9]. Critical parameters are the spectral transmission window, the optical loss, and the resistance of the fiber to high densities of light especially when the source is a laser. Since silica fibers are both reliable and inexpensive, the only market left is the region where they are no longer transparent. The lowest optical losses are found around 3 μm before transparency begins to decrease strongly in the 4–5 μm region.

Single-mode fibers are used in very special sectors such as spatial interferometry in the spectral region beyond 2 μm where silica fibers become opaque. Although the intense research made on ultralow-loss fibers for telecommunications has declined, the potential for ultratransparency is still a reality. The lowest loss obtained

in the 1990s was about 1 dB/km around 2.9 μm , but higher transparency would be possible through reduction in the IR thanks to a cutoff that is slightly shifted toward longer wavelengths, at 5.5 instead of 4.6 μm for optical fibers. In practice, the composition of these glasses is also complex with molar concentration of InF_3 close to 50% and various heavy metal fluorides (BaF_2 , PbF_2 , ZnF_2 , GaF_3 , or CdF_2) to keep the phonon energy as low as possible and to prevent crystallization from happening. Besides, small amounts of alkali chlorides can be also added to adjust the refractive index.

4.4 Active Properties

When the core of a fluoride fiber is doped with luminescent rare earth elements, the device can be considered as a

Figure 6 Optical configuration of a single-mode fluoride fiber used for laser action or optical amplification. Core glass doped with the appropriate rare earth ion.

new light source [4]. The optical configuration needs to be single mode to ensure the quality of the output light, whereas the specifications in terms of optical loss are as high as possible. The field was very active in the 1990s with the aim of developing two kinds of products, namely, optical amplifiers and fiber lasers. When a lanthanide is pumped with the appropriate source (a laser diode, for instance), the light emitted by the fiber is guided in its fiber, collected at the output (Figure 6), and serves to regenerate the telecom signal. For use as a laser, two mirrors are necessary to obtain the required oscillations.

The market of optical amplifiers is entirely driven by telecommunication constraints. Since the relevant wavelength is in the low-loss region of silica at $1.55\ \mu\text{m}$, the only rare earth operating in this region is the erbium ion Er^{3+} . Although the so-called erbium-doped fiber amplifier (EDFA) based on silica satisfies market needs thanks to their high efficiency, a potential for fluoride amplifiers resides in the use of other wavelengths located on the borderline of the silica low-loss region typically from 1.3 to $1.65\ \mu\text{m}$. Rare earth ions such as Pr^{3+} and Dy^{3+} are suitable for this region because the amplification ability is very poor in silica but very efficient in fluoride glasses. Compared with silica, however, a limitation of fluoride fibers is the impossibility of welding them with silica glass resulting from their chemical incompatibility.

Fiber lasers represent an expanding market because of their intrinsic advantages. Heat dissipation is, for instance, more efficient, whereas flexibility is fundamental to guide the light toward its target. The field is also dominated by silica fibers, which are strong and easy to prepare, but rare earths may have a weak luminescence in this matrix that suffers from poor transparency beyond $2\ \mu\text{m}$. Consequently there is some room for fluoride fiber lasers (Figure 7) as their emission range covers a broad spectral domain from UV to the mid-IR. The emission in the visible is due to *upconversion* or photon addition mechanisms, which are very efficient in this matrix.

Upconversion means that the ground-state electrons of the rare earth are first excited by photons pumped to an

upper long-life level. The same source can then promote these electrons to a higher level, from which light is emitted at wavelengths shorter than that of the pumping light. Pumping with an invisible IR source, for instance, results in the emission of a visible green light. Considering the power and the wavelength available from fluoride fibers (Figure 7), one sees that all these wavelengths are available for specific applications such as marking, cutting, or welding materials. Medical applications such as special surgery as well as analytical purposes are opening with this new kind of light sources

5 Chalcogenide Glasses

5.1 Formation with Chalcogens

Chalcogen glasses are built from S, Se, and Te, which lie below oxygen in the periodic table [6, 7]. Like oxygen, these elements are characterized by an outer electronic shell of six electrons, $s^2 p_x^2 p_y^1 p_z^1$, of which only the two odd electrons are involved in covalent bonding. Thus, these elements are generally twofold coordinated, generating crystal networks constituted of chains (Se and Te) or rings (S) in which the elements are strongly covalent bonded. The overall cohesion of these units is achieved through much weaker dipole–dipole van der Waals inter-chain bonds. Although the three chalcogens belong to the same family and share similar one-dimensional (1-D) crystal structures, they may be chemically “false friends” because sulfur and selenium are good glass formers whereas tellurium is not.

Although sulfur- and selenium-based glasses have similar chemistries, the former have a moderate interest because of their limited transparency in the mid-IR. Selenium thus is clearly the key element to form bulk glasses displaying the desired transparency in the mid-IR up to $16\ \mu\text{m}$. The strategies for glass formation are then the same as for fluoride in that they rely on empirical rules. The key ingredient is to form a polymeric melt with

Figure 7 Laser emission of rare earth-doped fibers. (a) Comparison between the emissions of fluoride and silica fibers. (b) Influence of the doping rare earth on the output power of fluoride fibers (from [6]).

highly flexible bond angles, thus yielding a floppy network keeping chemical bonds strong without periodicity.

In this respect, the structure of crystalline selenium is really unique as it is similar to that of an inorganic polymer. Its weak interchain bonds are easily broken by thermal agitation, hence a low melting point of 216 °C and the formation of a viscous liquid in which chain fragments persist. If Se is for this reason the only good glass-forming element, its glass transition temperature of 40 °C is much too low for any practical application. To increase it to ensure acceptable mechanical and thermal properties, a network dimensionality higher than 2 is required through chain cross-linking by elements close to selenium in the periodic table. In this way the covalent character of bonding is kept, and the strength of the structural network is improved. In practice, selenium chains are cross-linked

by trivalent elements such as As or Sb or tetravalent elements such as Ge, all of them having similar electronegativities. Two basic systems are then dominating the chalcogen-based glass scenery.

In the first (Se–Ge), the network is built with GeSe_4 tetrahedra connected to one another by Se chain fragments. The GeSe_2 composition yields a fully reticulated 3-D network where the tetrahedral units are directly corner shared. Because this stoichiometry is equivalent to that of SiO_2 in silicate glasses, one would expect GeSe_2 to be optimal in terms of viscosity and thermomechanical properties. On the contrary, its network is overconstrained because a lack of degree of freedom makes this glass difficult to form and unstable upon shaping. As for the GeSe_4 composition, its tetrahedral units are expected to be linked by Se–Se dimers providing the

needed flexibility to the network. As discussed in the Section 3.2, however, the structure of this glass is more complex, showing that chalcogenide chemistry may be complicated too.

In the second system (As–Se), the building blocks are AsSe_3 pyramids connected by bridging Se chain fragments. A fully reticulated network is obtained for As_2Se_3 , for which pyramids are expected to be directly linked by individual Se atoms. The resulting reticulated network has a 2-D planar shape and is floppy enough to provide a glass exhibiting good physical and rheological properties. This composition thus is one of the most widely used.

For technical and industrial uses, it is nonetheless advisable to oppose more strongly crystallization through more complex compositions bearing at least three elements. The so-called GASIR glasses belonging to the Ge–As–Se systems have, for instance, been developed by Umicore-IR glass company for molded IR optics. In these compositions the original 2-D planar network of the As–Se system extends into a third dimension through the GeSe_4 tetrahedral units incorporated, resulting in a T_g increase and in improved thermomechanical properties. The particular $\text{Ge}_{22}\text{As}_{20}\text{Se}_{58}$ composition is the most stable selenide, which makes it matchless for molded IR lenses. Other interesting materials belong to the Te–As–Se system, where addition of tellurium aims at lowering the phonon energy to shift transparency slightly further in the mid-IR comparatively with a purely selenide glass. An example is the $\text{Te}_2\text{As}_3\text{Se}_5$ glass whose network is formed of mixed Te–Se chains reticulated by trivalent As. It is stable enough to be shaped by the DIAFIR company into optical fibers for mid-IR spectroscopy.

As for pure tellurium [1], its very poor vitrifiability originates in the marked metallic character of the bonds that ensure interchain cohesion, which is, for instance, indicated by an electrical conductivity several orders of magnitude higher for Te than that for Se. This metallic character also results in a delocalized π bonding cloud, shorter interchain distances, and stronger cohesion of the structure and, thus, in a melting point of 422 °C much higher than 216 °C of Se. As observed for alloys, Te liquid is constituted of isolated, unreticulated atoms, which is why a glass can be obtained only by splat quenching.

5.2 Network Reticulation from Selenium Chains

In technologically important selenide glasses, bonding is highly covalent with small coordination spheres: Se (two-fold coordinated), As (3), and Ge (4). Despite this apparent simplicity, the structure of a glass network was until recently understood more from the solid-state chemist's intuition than from hard experimental data. It was commonly described as a network of covalent bonds obeying the 8-N rule, but no consistent information had been

obtained on medium-range order, i.e. on the actual connection of the AsSe_3 and GeSe_4 polyhedral building blocks. The reason was that X-ray and neutron diffraction data are not easy to interpret in chalcogenide systems because the sizes of the electronic clouds and, unfortunately, also the neutron-absorption cross sections are very close to one another for Se, As, and Ge. And because these elements are neighbors in the periodic table, the Se–Se, Ge–Se, and As–Se bond lengths are too similar to allow structural organization to be determined from RDF. A decisive step was thus taken when the first ^{77}Se solid-state nuclear magnetic resonance (NMR) spectra were collected in the $\text{As}_x\text{Se}_{1-x}$ and $\text{Ge}_x\text{Se}_{1-x}$ systems [10].

For As–Se binary systems, NMR results have more or less confirmed the chemist's expectations (Figure 8). From pure Se to the famous As_2Se_3 , the network of Se-rich glasses evolves from a 1-D chain structure to a 2-D pyramidal network. For pure Se, it has in particular been confirmed that the structure is built from selenium chains, as found in crystalline phases, so melting does preserve the strong intrachain covalent bonds and only de-solder the chains in a disordered but still reticulated network. For As_2Se_3 , the glass structure as seen by ^{77}Se solid-state NMR is also very simple: each Se does directly bridge the AsSe_3 pyramids, whereas a transition to a structure with a lower dimensionality is observed at the As_2Se_3 stoichiometry, beyond which As-rich glasses are composed of a pyramidal backbone containing an increasing number of 0-D As_4Se_4 or As_4Se_3 units. This transition has a direct bearing on thermal and mechanical properties that, as exemplified by glass transition temperatures (Figure 8), exhibit a clear extremum at the As_2Se_3 composition, consistent with its technological interest.

For Ge–Se systems, selenium atoms embedded into chain or ring fragments can be clearly identified from the band assigned to Se– ^{77}Se –Se neighbors in the NMR spectra. The intensity of this line is expected to decrease from pure Se to GeSe_4 stoichiometry. At this point all GeSe_4 tetrahedra should be bridged by Se–Se dimers, so the NMR spectrum should exhibit a unique band assigned to Ge– ^{77}Se –Se neighbors. As collected by different authors, however, ^{77}Se NMR spectra completely disagree with such chemist's expectations. In particular, they reveal a large contribution of selenium-chain fragments that include at least 33% of the Se atoms. In other words, weak van der Waals bonds are abundant in the GeSe_4 network, which was expected instead to be fully 3-D. This feature is the reason why the thermal, mechanical, or optical properties of this material do not have any special interest with respect to other glasses of the $\text{Ge}_x\text{Se}_{1-x}$ system. In conclusion, no composition in the Ge–Se system plays a role similar to that of As_2Se_3 in the As–Se system. Because of the lack of sufficient

Figure 8 Structure of chalcogenide glasses as determined by solid-state NMR. (a) Bands assigned to Se– ^{77}Se –Se, As– ^{77}Se –Se and As– ^{77}Se –As neighbors, illustrating the monotonously increasing reticulation of the network with the As fraction x . (b) Variation of T_g with the dimensionality of the structural network: maximum value for the most reticulated network of As_2Se_3 , followed by a decrease at higher As contents where molecular units appear to destroy the covalent network.

chemical ordering, the physical and structural properties increase monotonously until the GeSe_2 composition is reached, which is not a good glass former.

6 Chalcogenide Glass Applications

6.1 General Considerations

Thanks to their more floppy network, chalcogenide glasses have in general an excellent resistance to devitrification as indicated by a lack of crystallization peak in their DSC thermograms. Their glass-forming region is wide enough that glasses having a suitable viscosity-temperature relationship can be selected for particular applications. A curve with a gentle slope is suitable for molding and fibering. Bonding is strong enough to ensure a good durability with respect to water corrosion. Nevertheless parasitic absorption bands are very common. They are due to contamination by oxygen atoms, which are detected in the multiphonon region. Also Se-H absorption bands in the 4–5 μm region are difficult to eliminate. Purification operations, which require special expertise, are thus of paramount importance during synthesis.

Finally, the glass transition of selenide glasses is directly connected to the dimensionality of the structural network. The richer the glass composition in reticulating elements (As or Ge), the higher the T_g . Whereas T_g is 40 °C for pure Se glass, it increases to 185 °C for the fully reticulated As_2Se_3 (Figure 8). For GASIR, which is enriched in Ge, it reaches 280 °C, making this glass composition suitable for application in hazardous condition as requested by the military. On the other hand, glasses with low T_g are easy to prepare but are not suitable for applications. They have in particular too high expansion coefficients, which translates into a real risk of network relaxation even at room temperature.

6.2 Infrared Glass Molding

One of the factors limiting mass production of thermal-imaging systems such as night-vision devices resides in the high cost of traditional IR optics. These are made from ZnS transparent ceramics or Ge single crystals

through expensive fabrication processes that include high-precision diamond turning to obtain the final product. In this respect glasses have the obvious advantage of being directly moldable to the desired shape. Chalcogenide glasses have indeed ideal rheological properties for molding operations at moderate temperature and pressure. With easily duplicated silica molds (Figure 9), complex aspheric and diffractive optical configurations can be produced with a quality that makes direct installation of the parts in an IR camera possible.

Generally speaking, the definite advantage of chalcogenide over fluoride glasses lies in their much wider transparency in the mid-IR. In fibers, this transparency extends to at least 11 μm for selenide glasses and even 16 μm for telluride glasses against only 5 μm for the best fluoride. Most applications are restricted to selenide glasses, however, because tellurides are prone to crystallize and difficult to shape [1–3].

Chalcogenide glasses belonging to the domain Ge-As/Sb-Se have best thermomechanical properties through addition of tetravalent germanium, which causes the glass transition to rise sharply to the 250–300 °C range. These glasses do not absorb light in the 3–5 and 8–12 μm optical windows where the atmosphere is transparent enough to transmit blackbody radiation. They are thus used to make lenses for IR cameras mainly designed for thermal imaging and night vision. Original developments were made for defense purposes, but the cost of these advanced optics is declining, making applications possible in many civilian areas such as assistance in night driving or fire-fighting, heat-loss detection for energy savings, or body thermal imaging in human and veterinary medicines. Compared with the previously used crystalline Ge lenses, optics molded from chalcogenide glasses are much cheaper thanks to the reduced cost of the starting material and the more simply implemented hot-pressing technology. Technologically optimized compositions include the GASIR 1 (standard) and GASIR 2 (including Sb instead of As) IR glass optics developed and commercialized by Umicore-IR glass (Table 1).

In photonic applications, partial crystallization in the form of nanocrystals and even microcrystals can be advantageous, particularly with regard to mechanical properties. But the nucleation and growth steps of the glass ceramization process must of course be strictly

Figure 9 High-precision molding of chalcogenide glasses as lenses ready to be mounted in infrared optics.

Figure 11 The outstanding optical properties a TAS (Te–As–Se) glass fiber in the entire mid-infrared range. (a) Transmission. (b) Attenuation. Main parasitic absorptions due to oxygen and hydrogen (see the Se–H residual band at 4.8 μm).

Figure 12 Fiber evanescent-wave spectroscopy (FEWS). (a) Absorption of the energy propagating by reflection on the surface of the fiber by the sample to be analyzed. (b) IR source and detector positioned at the input and output of the fiber. With a reduction of the fiber diameter, the number of reflections and thus the sensitivity increase.

States. Because the expected signs of life on exoplanets are the presence of water, ozone, and carbon dioxide in their atmosphere, the targeted signatures are the mid-IR absorption bands of these gases at 6, 9, and 15 μm for H₂O, O₃, and CO, respectively. For their detection by space telescopes, single-mode fibers transmitting light from 4 to 20 μm must be manufactured. Such TAS glass fibers, which are the first presenting a single propagation mode at 10 μm, have been successfully designed and fabricated by the rod-in-tube method (Figure 5). As they stand, they are suitable for detecting H₂O and O₃ but not CO₂, which absorbs at 15 μm [1, 2]. Such research programs thus are a unique and challenging incentive for the development of glasses transmitting as far as possible in the IR. This feature is exemplified by Te-based glasses, which are the only vitreous materials having so broad an optical window from 2 to 22 μm and, thus, collecting light so far into the IR. Independently of any market-driven motivation, these space programs do show that the search for new exotic materials should not

depend only on expected applications to remain a goal for researchers in materials science.

7 Perspectives

Chalcogenide glasses are a wonderful playground for exploring the optoelectronic properties of amorphous semiconductors. Although their applications are currently exploiting their transmission in the mid-IR, further effort in basic and technological research should lead to more sophisticated functionalities in photonics based on a coupling of their optical and electronic properties [11]. Chalcogenide glasses, for instance, have nonlinear properties about 100 times larger than silica because the electron cloud of heavy elements is much more polarizable than that of oxygen and also because of a large amount of lone pairs in the glassy network. These effects should allow for supercontinuum generation, i.e. for large

secondary sources emitting in the mid-IR induced by pumping of sharp laser source. This goal has already been achieved with fluoride glass, but the emission domain is then limited by the glass transparency to 4–5 μm . At this time, a strong research activity focuses on the realization of such sources from chalcogenide glass fibers or planar guides.

Chalcogenide glasses are characterized by many other fascinating light-induced phenomena such as photo-darkening, photo-fluidity, photo-expansion, and photo-crystallization [12, 13]. All of them are induced by photons and not by thermal agitation. In any case, the wavelength of the exciting source must be close to the band gap of the glass to create electron–hole pairs that change the nature of chemical bonds and coordination numbers, triggering local structural reorganization. These phenomena are observable in the bulk but are magnified for thin films.

Of interest is also the electrical switching effect, which was originally discovered in telluride glasses as a purely semiconducting phenomena. The very first application consisted in playing with the optoelectronic properties of selenium as amorphous thin film to develop electro-photographic devices. In these applications, however, devices based on crystalline silicon or amorphous silicon thin films have prevailed [7].

Especially within the ternary Ge–Sb–Te–Te system, Te alloys can vitrify as thin layers of nm thickness but only upon ultrafast quenching. Under laser-beam irradiation they undergo readily the glass to crystal phase transformation, so they are very good candidates for optical storage. Although the digital versatile disk (DVD) technology is based on the reflectivity contrast between the vitreous and crystalline phases, it might alternatively rely on electronic conductivity in view of the differences of several orders of magnitude between the properties of the two phases. In addition, a challenging research activity is underway to form stable glasses for optics based on tellurium, in particular for IR sensing. Finally, one may note that, thanks to their easy shaping, chalcogenide glasses and glass ceramics containing Li^+ as a mobile ion have also a high potential as solid-state electrolyte for the development of batteries (Chapter 9.5).

6.6

Optoelectronics: Active Chalcogenide Glasses

Jong Heo¹ and Kai Xu²

¹ Department of Materials Science and Engineering, Pohang University of Science and Technology (POSTECH), Gyeongbuk, Republic of Korea

² State Key Laboratory of Silicate Materials for Architectures (SMART), Wuhan University of Technology, Wuhan, China

1 Introduction

From lenses and mirrors to optical fibers, glasses have traditionally been used as *passive* components in optics and photonics (Chapters 6.1, 6.4, and 6.5). But they can serve instead as spectral converters for *active* optoelectronic devices when they contain luminescent elements such as transition-metal and rare-earth ions. Among those active optoelectronic glasses, chalcogenides are unique because they are either used as matrices to host rare-earth ions or they constitute themselves luminescent sources in the form of the so-called quantum dots. Including from about 100 to 10 000 atoms in particles whose size ranges from several to tens of nanometers, these nanocrystals are incorporated in an amorphous matrix generally made up of silicate or phosphate glasses.

The first aim of this chapter thus is to present the most important features of rare-earth doped chalcogenide glasses for fiber-optic amplifiers and mid-infrared laser sources. As host materials, As–S, Ge–Ga–S, or Ge–Ga–Sb–Se chalcogenide glasses enhance the emission of light by rare-earth ions. The lifetimes of the excited electronic states of these ions depend much on whether or not their decays involve the simultaneous emission of multiple phonons. Because of their low-energy phonons, chalcogenide glass matrices thus ensure extended lifetimes for the excited electronic states of their host ions by making multiphonon relaxation difficult. Hence, they have potentials in fiber-optic amplifiers and mid-infrared lasers. The effect can be enhanced through addition of alkali halides such as KBr, KI, CsBr, and CsI to

chalcogenide glasses, in which cases a halide ion environment around a rare-earth ion further reduces electron–phonon coupling and, therefore, reinforce emission properties.

In the second part of the chapter, attention will be paid to quantum dots in transparent dielectric matrices. Because of quantum confinement effects, chalcogenide compounds such as CdS, CdSe, PbS, and PbSe present tunable optical properties when their size reduces to tens of nanometers. Glasses bearing quantum dots can thus cover a very wide range of wavelengths from the visible to the near-infrared, so they should give rise to universal fiber-optic amplifiers and color converters to be used in fields ranging from biomedicine (Chapter 8.4) to energy. Readers not familiar with these topics are referred to Chapter 6.5 for a detailed account on the structure and properties of chalcogenide glasses and to Chapter 6.3 for a review of spontaneous light emission in glasses.

2 Active Chalcogenide Glasses Doped with Rare-Earth Ions

Chalcogenide glasses doped with rare-earth ions have been considered as potential materials for mid-infrared lasers and fiber-optic amplifiers because of a low multiphonon relaxation compared with that of oxide glasses. This process competes against the desired emission, resulting in the reduction of the emission efficiency. It is more efficient in silica-based glasses whose intrinsic phonon absorption bands extend to the mid-infrared region. In contrast, chalcogenide glasses have relatively low phonon energies (Chapter 6.5, [1]) so that they can provide enhanced emission properties of certain fluorescence that are usually quenched in oxide hosts.

Reviewers: T. Wagner, General and Inorganic Chemistry, University of Pardubice, Pardubice, Czech Republic

X. H. Zhang, Institut des Sciences Chimiques, Université de Rennes I, Rennes, France

In a pioneering work, As_2S_3 glasses were used as hosts of different ions such as Nd^{3+} , Ho^{3+} , Er^{3+} , and Tm^{3+} [2]. Successful incorporation of up to 2.0 wt % rare-earth ions was achieved. In addition, mid-infrared fluorescences were reported, for instance, at 2098 and 440 nm from the Dy^{3+} cascading transitions ${}^6\text{H}_{13/2} \rightarrow {}^6\text{H}_{15/2}$ and ${}^6\text{H}_{11/2} \rightarrow {}^6\text{H}_{13/2}$, respectively. Since then many other infrared emissions have been reported from Nd^{3+} and Ho^{3+} in sulfide glasses. Much effort has also been devoted to Ge–Ga (with As)–S and Ga–La–S glasses because of the high rare-earth solubility in these matrices, good glass-forming ability, and partial transparency in the visible spectrum. Indeed, infrared emissions have been observed upon doping of these glasses with Ho^{3+} , Tm^{3+} , or Dy^{3+} [3].

Recently, emissions in the telecommunication wavelengths have also been investigated for applications toward fiber-optic amplifiers. Chalcogenide glasses doped with Pr^{3+} and Dy^{3+} ions have proven interesting thanks to an original O-band centered near 1300 nm [4, 5]. Much effort is done to develop materials for amplifiers at short band (S-band) and wavelength regions outside of the conventional band (C-band).

3 Optical Fiber Amplifiers

3.1 O-Band (1260–1360 nm)

Telecommunication Window

The 1300 nm emission from Dy^{3+} or Pr^{3+} ions was first observed in 1994–1995 in doped $\text{Ge}_{25}\text{Ga}_{5}\text{S}_{70}$ (at. %) glasses that had been melt quenched [4, 5]. Although this transition of Dy^{3+} has a larger stimulated emission cross section than that of the ${}^1\text{G}_4 \rightarrow {}^3\text{H}_5$ transition in Pr^{3+} [5], it suffers from the short 38 μs lifetime of its upper emission level (${}^6\text{F}_{11/2}$, ${}^6\text{H}_{9/2}$) so that its quantum efficiency of 17% is low. This lifetime is in fact approximately one tenth of that measured from the ${}^1\text{G}_4$ level in Pr^{3+} because of the high multiphonon rate of 25 000 s^{-1} of its ${}^6\text{F}_{11/2}$, ${}^6\text{H}_{9/2} \rightarrow {}^6\text{H}_{11/2}$ transition in sulfide glasses.

These drawbacks have been remedied via the addition to the glass matrix of small amounts of alkali halides [6],

Figure 1 Effect of the nature of the alkali halide added on the emission spectra for the 1310 nm (${}^6\text{F}_{11/2}$, ${}^6\text{H}_{9/2} \rightarrow {}^6\text{H}_{15/2}$) and 1750 nm (${}^6\text{H}_{11/2} \rightarrow {}^6\text{H}_{15/2}$) transitions in Dy^{3+} -doped chalcogenide and chalcohalide glasses [6].

which markedly enhance the intensity emitted by the transitions (${}^6\text{F}_{11/2}$, ${}^6\text{H}_{9/2} \rightarrow {}^6\text{H}_{15/2}$) at 1310 nm and (${}^6\text{H}_{11/2} \rightarrow {}^6\text{H}_{15/2}$) at 1750 nm (Figure 1). As reported early [4], the intensity of the 1310 nm emission in Ge–Ga–S glasses is considerably smaller than that centered at 1750 nm. In alkali halide-bearing chalcohalide glasses, however, the 1310 nm emission intensity clearly increases at the expense of the 1750 nm fluorescence band. The lifetime of the ${}^6\text{F}_{11/2}$, ${}^6\text{H}_{9/2}$ level is 1320 μs , i.e. it is approximately 35 times longer than that measured from Ge–Ga–S glass with a quantum efficiency approaching 100% (Table 1).

3.2 S-Band (1460–1530 nm)

Telecommunication Window

Other interesting materials are thulium-doped glasses. These have been investigated for S-band (1460–1530 nm) amplifiers to make use of the 1480 nm

Table 1 Calculated (τ_R) and measured (τ_m) lifetimes and quantum efficiency ($\eta = \tau_m/\tau_R$) of the 1310 nm fluorescence band in 0.1 at % Dy^{3+} -doped chalcogenide and chalcohalide glasses [6].

	0.9[Ge _{0.25} Ga _{0.10} S _{0.65}] –0.1KBr	0.9[Ge _{0.25} Ga _{0.10} S _{0.65}] –0.1CsBr	0.9[Ge _{0.25} Ga _{0.10} S _{0.65}] –0.1KI	0.9[Ge _{0.25} Ga _{0.10} S _{0.65}] –0.1CsI	Ge _{0.25} Ga _{0.10} S _{0.65}

η	0.88	>1	0.68	0.61	0.18

emission (Figure 2) from the $\text{Tm}^{3+}:^3\text{H}_4 \rightarrow ^3\text{H}_6$ transition [7]. Because the lifetime of the terminal emission level ($^3\text{F}_4$) is 8–10 times longer than that of the upper level, which hampers laser action, ways have been devised to achieve the required population inversion in Tm^{3+} ions, such as codoping with Ho^{3+} or Tb^{3+} ions [8]. As the energy gap between the $^3\text{H}_4$ level and the one located immediately below ($^3\text{H}_5$) is approximately 4300 cm^{-1} , the population of the $^3\text{H}_4$ level can alternatively be quenched through multiphonon relaxation. Glasses with low phonon energy must of course be used, namely, sulfides, fluorides [8], and tellurites [9]. But the amount of Tm^{3+} in glasses must be kept low, however, because the lifetime and population density of the $\text{Tm}^{3+}:^3\text{H}_4$ level is also quenched via cross relaxation ($^3\text{H}_4, ^3\text{H}_6 \rightarrow ^3\text{F}_4, ^3\text{F}_4$) when the Tm^{3+} concentration is high.

Chalcogenide and chalcogenide glasses containing CsBr provide viable solutions to these challenges. Three emission bands at 1220, 1480, and 1820 nm (Figure 2) are due to the $^3\text{H}_5 \rightarrow ^3\text{H}_6$, $^3\text{H}_4 \rightarrow ^3\text{F}_4$, and $^3\text{F}_4 \rightarrow ^3\text{H}_6$ transitions in Tm^{3+} , respectively. The 1480 nm emission intensity

Figure 2 Effect of the CsBr fraction x on the emission spectra of Tm^{3+} in $(1-x)(\text{Ge}_{0.25}\text{Ga}_{0.10}\text{S}_{0.65}) \cdot x\text{CsBr}$ glasses. Tm^{3+} concentration of 0.05 mol % in all glasses [7].

increases sharply and the lifetimes of the $^3\text{H}_4$ level also increase rapidly from 0.23 to 1.23 ms upon CsBr addition (Table 2), whereas the measured lifetimes of the $^3\text{H}_4$ level decrease with increasing Tm^{3+} concentration in all glasses. In $\text{Ge}_{0.25}\text{Ga}_{0.10}\text{S}_{0.65}$ glasses, the $^3\text{H}_4$ level lifetimes, for example, decrease from 233 to 93 μs as the amount of Tm^{3+} increases from 0.05 to 0.50 mol %. These changes are due to the increased rate of cross relaxation ($\text{Tm}^{3+}:^3\text{H}_4, ^3\text{H}_6 \rightarrow \text{Tm}^{3+}:^3\text{F}_4, ^3\text{F}_4$) as the average distance between Tm^{3+} ions decreases. Therefore, the concentration of Tm^{3+} should be carefully optimized to prevent such large lifetime decreases.

3.3 U-Band (1625–1675 nm) Telecommunication Window

Another important ion is Ho^{3+} , which has several mid-infrared and visible emissions whose intensities markedly vary with the nature of the host material [3]. The 1660 nm emission from the $^5\text{I}_5 \rightarrow ^5\text{I}_7$ transition is usually quenched in oxide matrices as a result of strong multiphonon interaction because the energy gap between the $^5\text{I}_5$ and $^5\text{I}_6$ levels is only 2600 cm^{-1} . An intense 1660 nm band has nonetheless been achieved in several chalcogenide glasses [10]. A large gain is realized within the U-band window (1625–1675 nm) in sulfide glasses doped with Ho^{3+} and Tb^{3+} ions. Since gain coefficients are directly proportional to the quantum efficiency of the specific transition, selenide and chalcogenide glasses are attractive host materials thanks to their phonon vibration energies that are as low as 250 cm^{-1} .

Excitation to the $^5\text{I}_5$ level of Ho^{3+} with a 910 nm laser beam results in a dominant near-infrared fluorescence at 2000 nm ($^5\text{I}_7 \rightarrow ^5\text{I}_8$) and in two additional bands centered at 1660 and 1180 nm (Figure 3). With an increasing Ho^{3+} concentration, the intensity ratios between the latter two emissions ($I_{1.66\mu\text{m}}/I_{2.00\mu\text{m}}$) considerably decrease probably because of the cross relaxation ($^5\text{I}_5, ^5\text{I}_8 \rightarrow ^5\text{I}_7, ^5\text{I}_7$). The measured lifetime of the $^5\text{I}_5$ level is 9.38 ms (Table 3) for a high quantum efficiency of ~99%,

Table 2 Spectroscopic properties of Tm^{3+} in various glasses [6].

Host glass	$\text{Ge}_{0.25}\text{Ga}_{0.10}\text{S}_{0.65}$	$0.90(\text{Ge}_{0.25}\text{Ga}_{0.10}\text{S}_{0.65}) - 0.10\text{CsBr}$	Fluoride	Tellurite

0.02	9.38	1
0.05	8.41	13
0.1	6.18	56
0.2	4.16	134

which represents clear evidence for the aforementioned small phonon energy of chalcogenide glasses.

3.4 Rates of Multiphonon Relaxation

The degradation of the lifetime and quantum efficiency of excited electronic states is assigned to multiphonon relaxation. Its rate (W_{mp}) for energy gaps (ΔE) of 900–3500 cm^{-1} has been calculated from the ratios

Figure 4 Dependence of multiphonon relaxation rates at room temperature on energy gap for phosphate: (a), silicate (b), germanate (c), tellurite (d), and fluoride (e) glasses. Solid lines: fits to the data calculated for Ge–Ga–S and Ge–Ga–S–CsBr glasses [7].

between the radiative and measured lifetimes. For sulfide and chalcogenide glasses (Figure 4), the ΔE and calculated W_{mp} data show the strongly beneficial effects of CsBr addition on both intensities and lifetimes. These data are described by the simple expression $W_{\text{mp}} = W_0 \exp(-\alpha \Delta E)$ where W_0 is the rate extrapolated to zero-energy gap and α a material-dependent constant. For both types of glasses, the rates for the excited levels are lower than found in oxide glasses by several orders of magnitude.

The temperature dependence of the multiphonon relaxation rates from the excited states of Dy^{3+} has been investigated to understand quantitatively changes in the local phonon mode. Up to approximately 150 K, the rates increase only slightly with temperature (Figure 5). At higher temperatures, they increase rapidly because of the stimulated emission of thermally activated phonons. Fits to the measured rates suggest that the five-phonon relaxation process of the 375 cm^{-1} vibration mode dominates in sulfide glass, whereas it is the six-phonon process of the 245 cm^{-1} vibration prevails in CsBr-bearing glasses (Figure 5a). Hence, these results strongly indicate that multiphonon relaxation originates in the stretching vibration of Ga–Br bonds in these glasses.

Figure 5 Temperature dependence of multiphonon relaxation rates in Dy³⁺ [6]. (a) From the ⁶F_{11/2}-⁶H_{9/2} level in Ge-Ga-S2 glasses. (b) From the ⁶F_{5/2} level in Ge-Ga-S2-CsBr glasses. Fits to the data made with five- or six-phonon relaxation processes.

3.5 The Influence of the Local Structure

Insights onto emission mechanisms can also be gained from studies of the local structure around the relevant ions, for instance, made with extended X-ray absorption fine structure (EXAFS) spectroscopy (Chapter 2.2). For Tm³⁺ ions, the L₃-edge EXAFS spectrum is similar in CsBr-bearing chalcogenide glasses and in crystalline TmBr₃. Representing the first neighbor shells around thulium in crystals, the main peak of the radial distribution function is observed at 2.74 (1) and 2.79 (1) Å (after phase correction) in TmBr₃ and Tm₂S₃, respectively (Figure 6). Because this peak becomes similar to that of TmBr₃ upon CsBr addition, one concludes that Tm³⁺ ions are mainly surrounded by Br⁻ ions in these chalcogenide glasses. From fits made to the EXAFS data, the sulfur coordination number of Tm³⁺ ions is in fact 6.77 (85) in Ge_{0.25}Ga_{0.10}S_{0.65} glass (Table 4). Upon addition of

CsBr, the first coordination shell around Tm³⁺ ions in contrast consists of ~5.86 (1.58) Br⁻ ions. This result again supports that the idea Tm³⁺ is predominantly surrounded by Br⁻ ions in CsBr-bearing chalcogenide glasses.

Large changes in emission properties upon CsBr addition suggest considerable modification of the local environment around rare-earth ions. The backbone of Ge-Ga-S glass is composed of edge- or corner-sharing GeS_{4/2} and GaS_{4/2} tetrahedra (Chapter 6.5, [11]). In CsBr-bearing glasses, Br⁻ ions seem to bond with Ga only. The bond energy is higher for Ga-Br than for Ge-Br whereas the bonding difference with S and Br is also larger for Ga than for Ge. Hence, Ga-Br bonds are energetically more favorable than Ge-Br so that the preferred coordination of Tm³⁺ ions with Br instead of S is likely related to the formation of [GaS_{3/2}Br]⁻ structural units in the glass matrix. In this case, [GaS_{3/2}Br]⁻ tetrahedral units need charge compensators, which are the rare-earth ions dissolved. These ions, therefore, ensure a reduced multiphonon relaxation and local refractive index compared with CsBr-free glasses, which significantly enhance emission properties [6].

4 Mid-Infrared Lasers

4.1 General Remarks

The mid-infrared range mostly refers to 3 000–25 000 nm wavelengths. It encompasses the atmospheric windows at 3 000–5 000 nm and 8 000–12 000 nm as well as the characteristic vibrational energy bands of most of gases, liquids and solids, including intermediate-reaction species and biological tissues (Chapter 6.5). Especially in the 3000–5000 nm interval, numerous mid-infrared laser sources have thus been studied for various applications including gas sensing, spectroscopy, chemical process monitoring, and military uses [11, 12].

Realistic high-power fiber lasers (>1 W) have been designed with Ho³⁺- or Er³⁺-doped ZBLAN optical fibers (Chapter 6.5), but they are operated at wavelengths shorter than 3000 nm where few applications are found. Although lasing above this wavelength is possible with ZBLAN glasses doped with Ho³⁺, Er³⁺, and Dy³⁺ ions, the high-power sources needed ensure only low outputs. Construction of a compact, high-powered, and economic all-fiber mid-infrared laser system is thus difficult with conventional fluoride glass fibers.

In this respect, chalcogenides are more advantageous than fluoride glasses. Not only are phonon energies lower than 350 cm⁻¹ for the former and higher than 500 cm⁻¹ for the latter, but chalcogenides show a wide transmission window extending to above ~10 000 μm. On the other hand, rare-earth ions such as Pr³⁺, Tb³⁺, Dy³⁺, Ho³⁺,

Estimated uncertainties in parentheses.

Er^{3+} , and Tm^{3+} have $4f$ – $4f$ transitions whose wavelengths lie in the 3000–5000 nm range. When pumped to the $^6\text{H}_{11/2}$ state, dysprosium has in particular a strong emission near 3000 nm with a three-level lasing system. It has also an emission near 4300 nm, which suffers from a high multiphonon relaxation rate in other glass hosts. Praseodymium covers a wide 3500–5500 nm range but requires a suitable host matrix because of narrow energy gaps between its $|4f\rangle$ states ($<2500\text{ cm}^{-1}$). Practical mid-infrared emission from those ions has mostly been reported from selenide glasses [11, 13] whose phonon energies are even lower than 250 cm^{-1} .

4.2 Dy^{3+} -Doped Chalcogenide Glasses

The characteristic emissions of Dy^{3+} ion in $\text{Ge}_{30}\text{Ga}_2\text{Sb}_8\text{Se}_{60}$ selenide glass are observed upon excitation with a 1.8 nm pumping source (Figure 7). The broad and strong emission bands at 2900 and 4300 nm are attributed to the $^6\text{H}_{13/2} \rightarrow ^6\text{H}_{15/2}$ and $^6\text{H}_{11/2} \rightarrow ^6\text{H}_{13/2}$ transition of Dy^{3+} , respectively, thus proving their

potentials as mid-infrared activators. Absorption by atmospheric CO_2 during the measurement was also found at $\sim 4240\text{ nm}$ [11].

The emission is further improved via the introduction of sensitizers that can effectively transfer energy to the $\text{Dy}^{3+}:^6\text{H}_{13/2}$ state by absorbing the pumping radiation. Possible candidates are Pr^{3+} , Tb^{3+} , and Ho^{3+} . With a 2050 nm excitation source, the effect is by far the most important for the 2900 nm emission of Pr^{3+} (Figure 8), probably through energy transfer between the $\text{Pr}^{3+}: (^3\text{F}_2, ^3\text{H}_6)$ and $\text{Dy}^{3+}: ^6\text{H}_{13/2}$ states.

Such a potential is witnessed by emission spectra measured from selenide optical fibers either doped with Dy^{3+} (0.02 mol %) only or codoped with Dy^{3+} (0.02 mol %) and Pr^{3+} (0.05 mol %) ions (Figure 9). These core-only fibers 25 cm in length were prepared by a modified double-crucible method and mechanically spliced to silica fiber pigtailed pumping sources. Their mid-infrared emission was monitored by condensing the light to the monochromator with a band-pass filter and a mechanical chopper. The potential for fiber laser operating at the wavelength

Figure 7 Emission spectra of Dy^{3+} in Ge-Ga-Sb-Se glasses for the concentrations indicated (mol %). Pumping wavelength of 1800 nm. Inset: ratio between the 2900 nm and total emission intensities against Dy^{3+} concentration.

Figure 8 Effect of 0.1 mol % codoping on the emission spectra of Dy^{3+} -bearing Ge-Ga-Sb-Se glasses. (a) Dy^{3+} doping only at 0.02 mol %. (b) Codoping with Ho^{3+} . (c) With Pr^{3+} . (d) With Tb^{3+} . All glasses pumped at 2050 nm.

of about 3000 nm is clearly shown by the strong Dy^{3+} emission centered at around 2950 nm out of Dy^{3+} ion observed upon excitation at 1800 nm. Unlike in bulk glasses, the band near 4300 nm decreases in intensity because of the combination of CO_2 absorption with a long interaction length (25 cm). The spectrum of the fiber codoped with Pr^{3+} also differs from that of bulk glasses when pumped at 2050 nm. The emission near 2900 nm is then suppressed because of the energy relaxation from the $\text{Dy}^{3+} : {}^6\text{H}_{13/2}$ level back to the $\text{Pr}^{3+} : {}^3\text{H}_5$ state that is taking place along the fiber.

4.3 Pr^{3+} -Doped Chalcogenide Glasses

Strong and broad emissions due to radiative transitions of (${}^3\text{F}_2, {}^3\text{H}_6$) $\rightarrow$ ${}^3\text{H}_5$ ($\sim 3.7 \mu\text{m}$) and ${}^3\text{H}_5 \rightarrow {}^3\text{H}_4$ ($\sim 4.7 \mu\text{m}$) are observed from Pr^{3+} -doped selenide glasses (Figure 10). Absorption by CO_2 near 4240 nm also takes place. Hence, it must be corrected to obtain real emission spectra [14] in the 3000 and 5500 nm range, which is highly useful for broadband sources and gain media in the mid-infrared. The broadness of the ${}^3\text{H}_5 \rightarrow {}^3\text{H}_4$ emission is mostly due to the many Stark split manifolds along with site inhomogeneity within the host matrix. In fact, the emission bandwidth increases with the Pr^{3+} concentration except for the one centered at around 3700 nm because of increased interaction among the excited states of Pr^{3+} ions. The measured fluorescence lifetime of the $\text{Pr}^{3+} : {}^3\text{H}_5$ state in selenide glasses is longer than 4 ms (Figure 10). Upon incorporation of Pr^{3+} ions, it displays a maximum at 0.02 mol % and then decreases. One has assigned this initial lifetime increase with Pr^{3+} concentration to increases of the population of the electronic ${}^3\text{H}_5$ states by cross-relaxation processes and the following decrease to energy transfer between Pr^{3+} ions made possible by reduced interionic distances. For practical use of Pr^{3+} ion as a mid-infrared activator, a compromise between lifetime

Figure 9 Emission measurements on a Ge-Ga-Sb-Se fiber doped with 0.02 mol % Dy^{3+} . (a) Experimental setup. (b) Effect of 0.05 mol % Pr^{3+} codoping on the emission spectrum (upper diagram: 25 cm fiber length and 1800 nm excitation; lower diagram: 15.5 cm and 2050 nm).

and bandwidth must be reached. Suitable doping concentration of Pr³⁺ in Ge–Ga–Sb–Se glass could, for instance, be 0.02–0.05 mol % to avoid these interactions between Pr³⁺ ions (Figure 10).

As already noted for Dy³⁺, mid-infrared emission by Pr³⁺ may be further enhanced by sensitizers such as Tm³⁺ and Ho³⁺ ions, which have similar absorption bands around 2000 nm. These do not have any lying energy levels lower than that of the Pr³⁺:³H₅ state, which can eliminate possible back energy transfer from Pr³⁺ ions that would enhance the quantum efficiency of the Pr³⁺:(³F₂, ³H₆) and ³H₅ states. In the emission spectra recorded from codoped selenide glasses (Figure 11), noticeable improvement is achieved with Tm³⁺. The highly efficient energy transfer from the sensitizer ion is due to the strong thermal coupling between the Tm³⁺:³F₄ and Pr³⁺:(³F₂, ³H₆) states along with the high absorption cross section of the Tm³⁺:³F₄ state. Upon pumping at 2050 nm, Ho³⁺ on the contrary decreases the mid-infrared emission of the Pr³⁺:(³F₂, ³H₆) level in spite of its energetic closeness with the Ho³⁺:⁵I₇ state. The effect can be attributed to a back energy transfer from the Pr³⁺:(³F₂, ³H₆) to the Ho³⁺:⁵I₇ level suppressing the radiative emission intensity. The lifetime of the 4700 nm emission decreases in the presence of Ho³⁺, but, consistent with the sensitizer effect, no considerable change is observed with Tm³⁺-codoped samples. In summary, these results point to a high potential of Pr³⁺/Tm³⁺-codoped selenide glasses as a mid-infrared gain media in the 3500–5500 nm region.

The feasibility of a fiber-gain medium has been also examined with the aforementioned optical fibers doped with 0.02 mol % Pr³⁺ [15]. For this purpose, experiments

Figure 11 Effect of codoping on the emission spectra of selenide glasses doped with 0.05 mol % Pr³⁺. (a) Starting glass. (b) Codoping with 0.2 mol % Tm³⁺. (c) With 0.2 mol % Ho³⁺. All glasses pumped at 2050 nm [14].

have first been made with a 1480 nm laser diode and a 2050 nm fiber laser to design the proper pumping scheme. The emission spectra then obtained are similar to those of the bulk glass, indeed proving the potential of the fiber as a gain medium when pumped at these two wavelengths (Figure 12). Upon pumping at 1480 nm, the emission peaks at around 5250 nm as determined by the second-order emission of the (³F₃, ³F₄) → ³H₅ transition. Pumping at 2050 nm is more favorable for the fiber laser, however, because of the distinct emission near 4700 nm and the detrimental effects of the 1480 nm excitation. When the fiber is excited up to the (³F₃, ³F₄) manifold, an excited-state absorption to ¹G₄ and other

Figure 12 Influence of the pumping wavelength on the fluorescence emission spectrum of a selenide optical fiber doped with 0.02 mol % Pr^{3+} [14].

higher-lying energy levels is likely to happen and to cause a depopulation of the $^3\text{H}_6$ and $^3\text{H}_5$ levels and, thus, to hamper gain development in the mid-infrared range. In any case, absorption by defects such as Ge—H (~ 4950 nm) and Se—H (~ 4500 and ~ 4750 nm) [11] can seriously impair the lasing action when a longer interaction length is required to improve the accumulated stimulated emission. Such impurities should thus be removed during glass and fiber fabrication through controlled refinement processes. Atmospheric contamination of the selenide fiber must also be avoided via passivation of the fiber with proper jacket materials.

5 Chalcogenide Quantum Dots

5.1 Fundamentals

Semiconducting CuCl, CuBr, CdS, and CdSe nanocrystals were first grown in a glass matrix by A. Ekimov and coworkers [16]. Since then, original quantum properties have prompted the synthesis of these new materials in colloidal solutions and, especially, the exploitation of the fact that changes in the size of chalcogenide quantum dots allow their spectral region to be widely tuned from the visible to the mid-infrared region. For optoelectronic applications, chalcogenide (CdX, PbX, X = S, Se, and Te) quantum dots are best incorporated in glasses, which possess themselves unique optical properties, high durability, easy processability, and compatibility with existing optical products.

When the sizes of semiconductor nanocrystals are comparable or smaller than the radius of their electron–hole pairs (i.e. their Bohr exciton), electrons and holes confined in all three spatial dimensions experience discrete energy states caused by confinement effects

Figure 13 The physics of a semiconducting quantum dot. (a) Zero-dimensional structure and density of state. (b) Continuous conduction and valence energy bands of a bulk semiconductor separated by a fixed energy gap, E_g . (c) Discrete atomic-like states energy levels of the quantum dot. (d) Influence of particle size on the band-gap energy [$E_g(\text{QD})$].

(Figure 13a). In a quantum dot, this confinement leads to a collapse of the continuous energy bands of the bulk material (Figure 13b) into atomic-like discrete energy levels (Figure 13c) whose well-separated states can be labeled with an atomic-like nomenclature (1S, 1P, 1D, etc.). As the quantum dot size increases, the band-gap energy also decreases (Figure 13d), resulting in a shift of the absorption and emission wavelength. These nanometer-sized semiconductor crystals are thus kinds of artificial atoms, which bridge the gap between cluster molecules and bulk materials.

As defined by the gap energy of the lowest exciton transition, the effective band gap $E_g(\text{QDs})$ can be estimated from the parabolic effective mass approximation [17]:

$$E_g(\text{QDs}) = E_g + \frac{\hbar^2 \pi^2}{2R^2} \left(\frac{1}{m_e^*} + \frac{1}{m_h^*} \right) - \frac{1.8e^2}{\epsilon R}. \quad (1)$$

In the first term, R is the radius of spherical quantum dots and E_g the band-gap energy of their bulk counterparts; in the second, the quantum confinement localization for electrons and holes is described in terms of m_e^* and m_h^* , the electron and hole effective masses, respectively; in the third, the Coulombic attraction, which is determined by the dielectric constant (ϵ), is negligible. Hence, the band-gap energy is simply proportional to $1/R^2$.

Table 5 Bohr exciton radii (a_B), band-gap energies (E_g), and wavelengths (λ) of the band-gap energies of CdX and PbX (X = S, Se, and Te) bulk semiconductors.

Semiconductor	a_B (nm)	E_g (eV) at 300 K	λ (nm)
CdS	3	2.53	490
CdSe	6	1.74	713
CdTe	7	1.50	827
PbS	18	0.41	3024
PbSe	47	0.28	4593
PbTe	50	0.31	4000

These data are summarized in Table 5 for bulk chalcogenide semiconductors. Because of small Bohr exciton radii and relative large band-gap energies, CdX quantum dots usually show a medium confinement and ensure tunable wavelengths in visible parts of the spectrum through a surface effect. In contrast, PbX semiconductors possess large Bohr exciton radii and narrow band-gap energies, resulting in a strong confinement and tunable wavelength in the near-infrared with a smaller surface effect.

5.2 Optical Properties of Quantum Dots in Glasses

As quantum dots get smaller, their effective band-gap energy increases. As a result, the exciton transition shifts to shorter wavelengths, which offers a convenient way to tune their absorption and photoluminescence wavelengths through size changes. In a silicate glass containing PbS quantum dots of different sizes (Figure 14), the onset of light absorption shifts from ~ 1000 to ~ 2000 nm when the radius increases from 1.9 to 4.6 nm. Relative to the lowest absorption peak (Figure 14b), the emission undergoes a Stokes shift to the red with the same tunability. Theoretical work has been done to account for the dependence of the band-gap energy on the particle size in terms of a parabolic effective mass mode, Eq. (1), a hyperbolic-band approximation, a tight-binding model, or an envelope wave-function calculation.

In addition to size, external fields such as temperature can also influence the band-gap energy. For virtually all semiconductors, the temperature dependence of the band-gap energy is well known experimentally. It includes contribution from the lattice thermal expansion and electron–phonon interactions in bulk semiconductors, but depends strongly on particle size. Both effects become insignificant when the energy levels are determined more by the structure than by the lattice constants and the spacing between the quantum-confined energy

levels increases. For the lowest exciton energies of PbS quantum dots of different sizes in glass and polymer matrices, the dE_g/dT measured from 12 to 300 K is actually almost zero for the smallest particles and approach the bulk value of $\sim 500 \mu\text{eV/K}$ only for largest [18]. The temperature independence of the energy gap for the smallest dots thus is a direct consequence of strong quantum confinement.

Owing to high surface to volume ratios, unsaturated or dangling bonds at the particle surface act as surface traps for charge carriers. As a consequence (Figure 15), electron and hole pairs recombine not only directly within quantum dots (Band I of the photoluminescence spectrum) but also on surface traps, resulting in nonradiative or deep trap emission on the low-energy side of the band edge (Band II). Because of the small Bohr radius of CdS, a two-band photoluminescence can be easily observed in the room-temperature spectrum of this quantum dots in a silicate glass. When the particle size increases, the intensity of trap emission decreases as surface atoms become relatively less numerous.

To reduce surface trap states, dangling bonds at the surface of quantum dots must thus be passivated. Trioctylphosphine oxide $[\text{OP}(\text{C}_8\text{H}_{17})_3]$, TOPO and trioctylphosphine $[\text{P}(\text{C}_8\text{H}_{17})_3]$, TOP are the most frequently used organic passivating groups for CdSe. Passivation of surface defects can also be achieved with the deposition of an inorganic shell semiconductor onto the core quantum dots in the so-called core/shell structures. The shell material then has a wider band gap than the core quantum dots, also enhancing carrier confinement. It is difficult to passivate the entire surface of quantum dots in a glass, however, so surface effects remain significant and result in a lower luminescence efficiency. A quantum yield as high as 50% has nonetheless been achieved recently for CdSe/ $\text{Cd}_{1-x}\text{Zn}_x\text{Se}$ core/graded shell quantum dots [19] and for CdS/ $\text{Cd}_{1-x}\text{Zn}_x\text{S}$ sandwich-structured quantum dots [20] in glasses, whereas an efficient intrinsic emission from CdSe and CdS nanocrystals was observed.

5.3 Fabrication of Glasses Containing Quantum Dots

5.3.1 Methods and Matrices

Quantum dots mainly form in glasses through the decomposition of solid solutions that become oversaturated. In the most convenient and inexpensive method, the glass batch and semiconductor are mixed and melted at high temperatures to form a precursor glass, which is then annealed near or above the glass transition. These treatments promote the nucleation and diffusion-controlled growth of semiconducting nanocrystals (Chapter 5.4) and cause the absorption and

Figure 14 Absorption spectra of PbS quantum dots in a silicate glass. (a) Shift toward higher wavelengths with increasing particle size (1.9–4.6 nm). (b) Absorption and photoluminescence spectra for an average particle radius of 1.9 nm.

photoluminescence peaks to shift with higher temperatures or longer process durations (Figure 16) [21].

The solubility of chalcogenides is smaller than ~1 mol % and about 5 mol % in silicate and phosphate glasses, respectively (Table 6). The former matrices are most frequently used because of their high durability and easy processability. Because the glass batch is then typically melted above 1300 °C, some extra chalcogenide is added to compensate for partial volatilization. Alternatively, phosphate matrices are selected to increase the concentration of chalcogenides and reduce their volatilization at lower melting temperatures of about 1100 °C before annealing at around 400 °C. Owing to higher solubilities and ion mobilities, however, the growth of quantum dots is more difficult to control in phosphate than in silicate glasses.

Two other techniques have been developed for incorporating quantum dots in glasses. With sol–gel methods (Chapter 8.2), the most efficient manner is to prepare quantum dots by a colloidal technique and to introduce them in the sol before aging or deposition as a

Table 6 Compositions and preparation of PbS-, PbSe-, and PbTe-doped glasses.

See [22] for cadmium chalcogenides.

silica-doped film. But bulk glasses cannot be obtained in this way. Ion implantation is another surface method. Quantum dots form upon heat treatment after accelerated ions have been implanted at depths of a few hundreds of nanometers. For example, lead chalcogenide quantum dots are synthesized by sequential implantation of Pb and one of the chalcogen species into pure silica [23], followed by annealing at 850–900 °C for one to eight hours to reach a maximum concentration of about 0.3 at. %.

5.3.2 New Strategies

In optoelectronic applications, it is important to control not only the size but also the distribution of quantum dots. Rare-earth ions are thus widely used as nucleating agents. The number of PbS quantum dots is, for instance, 251 and 1025 per μm^2 as measured from a 2-D TEM micrograph in glasses containing 0 and 0.2 mol % Er₂O₃, respectively, after annealing at 500 °C for 20 hours (Figure 17) [22]. Addition of rare-earth ions causes both the absorption and photoluminescence peaks of PbS to shift to the shorter wavelengths, indicating that the size of PbS quantum dots then decreases.

A similar effect is achieved with Ag nanoparticles, which in addition provide an alternative method to form

quantum dots at a depth of only tens of microns below the glass surface by diffusion of Ag⁺ ions from AgNO₃ melt or a silver paste. The specimens are then heated first near 350 °C to precipitate Ag nanoparticles and then at about 420 °C to precipitate quantum dots only in the Ag⁺-affected regions. The amount of Ag migration into the glasses as well as the size of PbS dots can be controlled through adjustment of the temperature and duration of the annealing. The method is particularly effective for site-selective formation of lead chalcogenide quantum dots in glasses for planar or waveguide photonic devices.

Femtosecond laser irradiation is another useful method for ensuring ion diffusion through local accumulation of heat. By a Soret effect, the concentrations of network formers increase in the irradiated region as a result of out-diffusion of the small network modifiers. Upon femtosecond laser irradiation, cadmium/lead and chalcogenide species thus redistribute and precipitate as quantum dots with a controlled spatial distribution. For example, a laser with a pulse width of 184 fs can be used at a repetition rate of 1 kHz and a pulse energy of 247 μJ to irradiate the glass specimen and form 50 μm underneath its surface a 2-D square (2×2 mm) pattern consisting of 1600 spots separated by 50 μm . After irradiation of each spot by 200 pulses, the glass specimen heated at 420 °C for 20 hours

Figure 17 Evaluation from TEM image analyses of the number density of PbS quantum dots in borosilicate glass annealed at 500 °C for 20 hours [22]. (a) Glass without Er_2O_3 doping. (b) Glass doped with 0.2 mol % of Er_2O_3 .

has precipitated large, dense PbS quantum dots and shows strong color changes in the irradiated compared with the non-irradiated regions. A strong photoluminescence peaking at ~ 1200 nm is indeed observed in the irradiated region, whereas only a weak emission band occurs at ~ 1100 nm elsewhere.

5.4 Potential Applications

Chalcogenide quantum dots have a short relaxation time made up of two components, a fast in the tens of picosecond range and a slow one in nanoseconds. Therefore, glasses containing dots with different sizes have been used as saturable absorbers in a wide range of wavelength (e.g. CdS/CdSe/CdTe quantum dots, 510–850 nm; PbS/PbSe, 1000–2000 nm) under different operating laser conditions. A detailed study of the use of such saturable absorbers for passively mode-locked and Q-switched solid-state lasers can be found in [24].

Glasses containing chalcogenide quantum dots can also be used as active optical components such as LED color converters (Chapter 6.9) and fiber-optic amplifiers utilizing their tunable photoluminescence from the visible to the infrared range. A white LED color converter with CdSe quantum dot-doped silicate glass has, for instance, been successfully fabricated [25]: the heat-treatment conditions have been optimized in terms of the size of quantum dots through which the white light can be observed when the doped glasses are mounted on a 450 nm blue LED chip. One can then adjust the CIE (Commission Internationale de l'éclairage) color coordination of the device by varying the size of CdSe quantum dots through controlling the heat-treatment conditions (Figure 18). The color coordination thus moves from blue to red as the annealing duration increases up to 15 hours. Compared with the phosphor-embedded organic resins

commercially used, these glasses thus provide thermally and chemically more stable matrices, thereby eliminating the problem of resin degradation (Chapter 6.9).

Glasses containing lead chalcogenide also have the potential to become universal fiber-optic amplifiers in the telecommunication network where rare-earth doped amplifiers are most successful. As determined by the electronic structures of rare-earth ions, however, their amplification windows are narrower than 100 nm. By tuning the size of lead chalcogenide quantum dots, one can in contrast cover the whole 1260–1675 nm optical telecommunication window. Optical amplification at 1330 and 1550 nm also obtains in bulk glasses containing PbS quantum dots. In practice, a problem met during fiber drawing is uncontrollable growth of the dots, but it has been solved by a melt-extraction method with which the transparent precursor glass fiber is made [26]. In this way, near-infrared emission has been obtained from heat-treated fibers doped with PbS.

6 Perspectives

Interestingly, the coloring effects in stained glass of Cd and Se tiny particles became known empirically in late nineteenth-century Art Nouveau, i.e. well before the discovery of quantum dots [27]. Since then the interest has shifted to the intensity, lifetime, and other radiative properties of light emission from rare-earth ions in chalcogenide and chalcohalide glasses, which have a definite potential for amplifiers in fiber-optic communications. For example, the lifetime and intensity of the 1.31 μm emission level (${}^6\text{F}_{11/2}$ – ${}^6\text{H}_{9/2}$) in Dy^{3+} are significantly higher in chalcogenide and chalcohalides than in other glasses. Rare-earth ions in sulfide glasses are mainly surrounded by approximately seven S ions whereas they were coordinated by $\sim$ six Br ions in chalcohalide glasses

Figure 18 Effect of the size of CdSe quantum dots in silicate glass on LED color converters [25]. (a) CIE color coordination after annealing at 520 °C for varying durations; actual photographs of the LEDs displayed on the right-hand side. (b) Electroluminescence spectra of the LEDs. (c) Photoluminescence spectrum and overlap between the absorption and emission spectra of the glass annealed for 30 hours.

containing CsBr. Hence, they experience a reduced electron–phonon coupling that enhances emission properties.

Thanks to their low phonon energy and high transparency, chalcogenide glasses are also highly promising materials for mid-infrared gain media when doped with rare-earth ions. Characteristic emission band at 3000 and ~4300 nm and a broad feature between 3500 and 5500 nm are observed from Dy^{3+} and Pr^{3+} doped Ge–Ga–Sb–Se glasses, respectively. Codopants such as Pr^{3+} , Ho^{3+} , and Tb^{3+} further improve the emission via efficient energy transfer to the active ion. The Tm^{3+} ion is also beneficial to Pr^{3+} ion upon pumping at 2005 nm to enhance the mid-infrared emission due to the $^3\text{H}_5 \rightarrow ^3\text{H}_4$ transition. Likewise, Dy^{3+} - and Pr^{3+} -doped selenide optical fibers produced display mid-infrared emission promising for laser materials.

Glasses containing chalcogenide quantum dots have been extensively investigated over the past three decades. Efforts have focused on the quantum size effect, size control, absorption, and photoluminescence properties and on the development of new applications. The main challenge to overcome includes improvements of currently low luminescence efficiencies resulting from defects at the interface of the quantum dots with the glass matrix.

These surface defects give rise to nonradiative recombination or trap emission and, thus, reduce direct recombination from electrons and holes. It is difficult, although not impossible, to passivate the surface of quantum dots because they are isolated by the glass matrix from the beginning of the nucleation stage. Innovative methods need to be developed to modify these surface defects if one were to realize high-efficiency optical devices. Another challenge is to avoid the secondary growth of quantum dots during the fiber-drawing process. When drawing PbS-doped glass fiber from the preform, such a secondary growth occurs at elevated temperatures. Although this growth can be controlled with melt-extraction methods, it can be done only to bare fibers. For practical applications, the drawing process must thus be modified so as to produce glass fibers doped with quantum dots that have an outer cladding layer.

Acknowledgments

We warmly thank Woon Jin Chung, Xiang-Hua Zhang, Animesh Jha, and Thomas Wagner for their very helpful reviews of this chapter.

1 Introduction

That surfaces have special properties was made clear when Newton [1, 2] reported in 1686 that two flat glass plates pressed together could hardly be separated and that some liquid inserted between the plates made separation still more difficult. The origin of such phenomena long remained enigmatic even though it had to be related to the differing arrangement of atoms or molecules at the surface and in the bulk of a solid. The changes in the physical and chemical properties of surfaces are not limited to their topmost monolayer, however, but to a more or less extended transition region. Many investigations of these properties have been undertaken but only a few monographs concerning the properties of glass surfaces were available as late as the 1960s [3, 4].

Early experiments concentrated on the attractive forces investigated by Newton. Macroscopic degradation such as corrosion, abrasion, and wear had been observed on the surface or in near-surface regions for different glasses but a microscopic understanding of such effects was limited because surface-sensitive analytical tools were not available. It was nonetheless known that various factors influence the nature of a glass surface and that, even for the same material, different forming methods produce different surface properties.

Chemists investigated the interactions between the surfaces of solids and liquids or gaseous ambient surrounding it. For example, the various forces involved in physisorption, chemisorption, and chemical binding had been measured, and their origin explained. But physicists were

not interested in contamination effects. They considered the structure and prevailing binding forces in solid-state materials ideal for research but systematic investigations were hampered by adsorbed foreign layers of unknown compositions. The situation changed in the 1980s when the development of ultrahigh vacuum (UHV) technology allowed fresh solid-state surfaces to remain clean for several hours. This advance led to a new research area, surface physics, and to an improved understanding of various phenomena at glass surfaces. These were, for instance, reviewed during a conference entitled *The Surface: A Bug in New and Old Glasses* organized in 2000 in Venice by P. Mazzoldi in cooperation with Technical Committees of the International Commission on Glass (Chapter 9.11).

Today, many issues pertaining to technical materials are accepted as surface problems whereas improved surface properties are themselves seen as offering many opportunities for glass applications. Therefore, considerable research has been invested in recent decades in studying surfaces and developing technologies for glass-surface treatments whose success also depends on understanding better simple age-old procedures like grinding, polishing, structuring, and cleaning.

Surfaces are described in many ways. Mathematicians may see them as two-dimensional topological manifolds whereas solid-state physicists may refer to the broken symmetries of the bulk. But such definitions limit the complexity to one view and ignore the physical and chemical phenomena that occur particularly at solid-liquid and solid-gas interfaces. A real glass surface can be described macroscopically by an abrupt change between solid glass (defined by its chemical composition and production history) and the surrounding medium (which influences the history). Microscopically, however, there is no abrupt boundary but different transitional zones with specific compositions and structures between

Reviewers: J. M. Parker, Department of Materials Science and Engineering, Sheffield University, Sheffield, UK
V. Rupertus, Central Research and Technology Development, Schott AG, Mainz, Germany

the glass and its environment, which depend on many parameters. Chemisorbed water, for instance, dominates the chemistry of silicate glasses from the bulk to the glass surface through the near surface region. In multicomponent glass systems, this feature leads to in-depth hydration, surface layer formation, and corrosion (Chapters 5.11 and 5.12). Beginning with manufacture, slow alteration of the glass surface is a universal and never-ceasing phenomenon. These changes depend on the interactions with the environment, time of exposure, temperature, and other conditions. These natural responses of a surface to the manifold interactions with the different contacting media are the basis for very powerful surface technologies, which can be used to manipulate the properties of the glass.

Most physical and chemical properties of glasses are influenced by special surface treatments so that specific functionalities for various applications can be created. For example, the mechanical properties of glass are of fundamental importance. Because surface defects cause the practical strength to be far below its theoretical value (Chapters 3.11 and 3.12), their effects can be minimized by the deposition of thin films or by compressive stresses resulting from chemical modifications of surface layers by ion exchange.

Many surface technologies are available (Figure 1). They can be categorized as (i) removal of material from the surface by mechanical, optical, or thermal treatment; (ii) exchange of species from the glass with the environment by chemical or physical driving forces, for instance, by diffusion; (iii) addition of material by different coating processes (Chapter 6.8). The choice depends on the requirements of the applications. Since the market value of glass products will increasingly depend on their surface properties, even more technologies are under development. This chapter thus describes the fundamentals of the underlying processes and their applicability. Surface properties are first determined by the glass-forming

process because pressing, blowing, drawing, or floating yield characteristic properties that differ for the same bulk composition. At the hot end of production, additional processes can then modify the surface, for example, to facilitate handling of the virgin products or to reduce corrosion as will be exemplified here with dealkalization and flame polishing. The influence of glass forming and hot-end processing on surface quality will thus be discussed. Relevant technologies will also be explained, including surface cleaning, polishing, structuring, ion exchange, and thermal treatment and examples of their use for traditional products and more advanced applications will be presented.

2 Hot-End Processes in Glass Production

2.1 Dealkalization

When glass is in contact with water, aqueous solutions, or humidity, its morphology and composition change in the surface region as described by two kinds of corrosion reactions (Chapter 5.11, [5]). The first is an ion-exchange reaction (leaching) between network-modifying ions such as Na^+ in the glass and H^+ ions in water resulting in the formation of Si-OH groups, the release of network modifiers, an enrichment in hydroxide ions and, thus, a pH increase:

Once the pH reaches 9 or more, hydrolysis begins to generate silanol and non-bridging oxygens:

As discussed in Chapter 5.11, these reactions can take place right after production during transportation,

Figure 1 Basic processes of glass-surface technology.

storage, and even final use if the glass temperature falls below the dew point of the atmosphere [6], in which case the chemical and physical properties of the surface differ from those of the bulk [7]. The various ways available to prevent the problem or limit its consequences have also been described in Chapter 5.11. Here, we will thus restrict to the problems raised by diffusion of mobile Na^+ ions toward the surface that cause defects such as fracture and cavities and affect the chemical and mechanical reliability of coatings through poor adhesion, phase changes, film delamination, and optical deterioration [8]. A common way to reduce corrosion is the century-old dealkalization process whereby a thin surface layer depleted in sodium is created through reaction with SO_2 gas in the presence of water [9, 10]:

The rate of this exchange reaction between Na^+ ions in the glass and hydrogen ions is limited by the diffusion of Na^+ ions to the surface where a film of water-soluble Na_2SO_4 crystals is deposited. This rate is increased if the mixture is passed over a vanadium pentoxide (V_2O_5) catalyst at a temperature high enough to oxidize SO_2 into SO_3 before contact with the glass surface [11]:

For a typical soda lime silica (SLS) float glass, the Na depletion is clearly observed in X-ray photoelectron spectroscopy (XPS) down to a depth greater than 80 nm, which compares with the 15–25 nm found for the untreated glass [12].

In the float process, dealkalization on the atmosphere and tin sides of the sheet is performed above 500°C during annealing and at the tin bath exit near 600°C , respectively. More Na is in fact eliminated on the former than on the latter side where the presence of Sn reduces the diffusivity of the mobile Na^+ ions. On the other hand, dealkalization of the tin side improves not only corrosion resistance but also surface quality because the deposited Na_2SO_4 film acts as a lubricant to protect the glass surface and heal surface defects, microcracks, or scratches created by the contact with the rollers. Complications may arise, however, and, for instance, result in local defects because the deposition of the Na_2SO_4 film depends on parameters like water content, SO_2 concentration, and temperature so that metastable

forms of Na_2SO_4 can be generated under unfavorable operating conditions [13].

In the glass-container manufacturing process, dealkalization is applied at temperatures above 500°C to achieve a higher hydrolytic resistance of the interior surface. The resistance is measured by titration with an acid solution according to the international standard ISO 4802-1 (Chapter 5.1). There are other dealkalization methods. When solid $(\text{NH}_4)_2\text{SO}_4$ or aqueous solutions are introduced within the container after forming, they decompose above 500°C in the annealing lehr to produce the SO_3 gas needed for the dealkalization reaction [14]:

The method is ecologically safe since unreacted components do not escape to the atmosphere. Rather, they react with each other to form the original salt in the container, which can later be rinsed away. The drawback of the process is fracture of glass because solid $(\text{NH}_4)_2\text{SO}_4$ or aqueous solutions may cause the glass to supercool and break it.

2.2 Flame Polishing

Surface quality is one of the most important constraints to be respected by tableware and container manufacturers. For pieces produced by press technology, flame polishing is most widely used to improve it. By impinging on the surface and remelting a thin layer (Figure 2), flames allow specific regions to be heated precisely for eliminating surface defects like burrs, sharp edges, stains, and cracks, minimizing surface roughness and enhancing brilliance. The improvement is obvious in optical profilometry images of glass surfaces (Figure 3). Additional advantages of the method are to eliminate the usage of either mechanical processing or acid polishing with hazardous chemicals like HF and to make automatically produced glassware resemble handmade pieces.

Figure 2 Flame polishing in production.

Figure 3 Optical profilometry images of glassware surface that is formed by the press process: comparison between the initial rough state (a) and the smooth and almost defect-free state after flame polishing (b) [15].

Process parameters for flame polishing are the gas flow, heat transfer rates, working distance between burners and glass surface, flame shapes, gas ratios, and pre- or post-mixing of gases. If these parameters are improperly chosen, surface defects can form on some parts of the surface, which may get corroded after a certain number of cycles in a dishwasher (Figure 4). This corrosion has been assigned to alkali enrichment of the surface upon flame polishing and subsequent hole formation that manifests itself as partial surface clouding after dishwashing [16]. The phenomenon has been more precisely described with the help of atomic force microscopy (AFM) and other high-resolution analytical techniques [17]. In remelted areas, alkali and alkaline earth ions may evaporate to condense on colder regions (Figure 5). In the form of holes (Figure 6), preferential dissolution of these areas in the dishwashing environment then causes the observed clouding (i.e. light scattering).

Figure 4 Glassware partially corroded (in the middle part) during dishwashing as indicated by the scattering of light caused by the presence of numerous holes.

Figure 5 Sketch of the flame-polishing process: evaporation and condensation regions.

3 Cleaning

Glass surfaces can be contaminated by inorganic or organic matter found as particles or as films and brought by gases, liquids, or solids present in the atmosphere and other media. Not only is the number of sources nearly unlimited but also the bulk glass is often contributing to the contamination by diffusion. Different phenomena like adsorption, chemical reactions, leaching and drying procedures, mechanical treatment, as well as diffusion and segregation processes can give rise to surface contaminants of various compositions. Cleaning of glass surfaces thus is a serious issue. At the atomic scale, the clean

Figure 6 Holes about 1 μm in diameter formed after dishwashing as seen in height-mode AFM images of a glass surface 3–4 mm away from a flame-treated area. Scratches and contamination fragments only observed before flame polishing.

surfaces needed for scientific purposes, for example, to study interaction mechanisms, can only be obtained under an UHV. Because these conditions are not relevant industrially, we will deal here with the *technically clean* surfaces required not only for tableware, windows, smart phones, or eye glasses but especially for surfaces that must be coated with thin films in a variety of scientific or technical applications [18]. Because no universal cleaning methods exists, however, all are tailored to specific glass surfaces and a combination of them is often required to achieve the cleanliness required by the application of interest.

Different techniques are thus used depending on the contaminant, glass type, and dimension of the pieces. Usual methods involve scrubbing or polishing the surface in combination with various cleaning fluids. Traditionally a pre-cleaning operation consists in rubbing the surface to remove any dirt as done for eye glasses, lens, or mirrors with a tissue saturated with an appropriate fluid. The type of glass and the nature of the contaminants determine which solvent is to be applied in the liquid or vapor state and at which temperature. These solvents include deionized water, aqueous solutions of detergents, diluted acids or bases at various concentrations, and nonaqueous solvents such as alcohols, chlorinated or fluorinated hydrocarbons.

A simple and common technique is immersion or dip cleaning whereby the wetted glass pieces are removed from the solvent tank after a short time and dried. For certain glasses, chemical reactions are also exploited with various liquids under a wide range of pH values. Most acids are used warm between 40 and 80 $^{\circ}\text{C}$. Silica is not readily dissolved by acids, except by hydrofluoric acid.

Higher temperatures may aid silica dissolution so that a fresh surface is created on the glass. Acid cleaning cannot be used for all glass types.

As used since about 1950, ultrasonic (US) cleaning is particularly effective to remove in a few seconds or a few minutes strongly bonded contaminants such as pitch and polishing-agent residues from optically worked glass. Cleaning is performed in a tank containing the appropriate solvent usually kept at about 40–65 $^{\circ}\text{C}$ and equipped with transducers that convert an oscillating electrical input into ultrasound waves of 20–400 kHz frequencies. The compression waves propagating in the solvent create microscopic “voids” or “partial vacuum bubbles” (cavitations), which remove surface dirt and contaminant by collapsing onto them with a high-energy density. The higher the frequency, the smaller the nodes between the cavitation points and the more intricate are the structures that can be cleared. In addition, one can of course increase the cleaning efficiency by increasing the power input and cavitation density.

Many thin-films are deposited under vacuum. Procedures have thus been developed to clean surfaces prior to coating under the same conditions. Vacuum does cause evaporation of volatile impurities, but the process depends on the remaining pressure, duration, substrate temperature, and type of contaminant. Glass surfaces are traditionally heated at 100–350 $^{\circ}\text{C}$ for 10–30 minutes before coating to remove part of the water and various hydrocarbon molecules adsorbed. Atomically clean surfaces require an UHV and temperatures higher than 450 $^{\circ}\text{C}$ so that other techniques have been developed to import more energy onto glass surfaces. For instance, an ozone-producing UV source rapidly decomposes hydrocarbons on properly pre-cleaned surfaces. The highly reactive oxygens produced by ozone actually react with the free radicals produced by the dissociation of the contaminant to form volatile molecules like H_2O , CO , and N_2 .

Electrical-discharge cleaning at a reduced pressure immediately prior to film deposition is also widely used. With plasma cleaning, impurities and contaminants are removed by reaction with excited atoms and ions formed at typical kHz to MHz voltage, which emit a characteristic light-glow when they return to their electronic ground state. Be they atoms, molecules, ions, electrons, free radicals, and vacuum UV photons, the various activated species present in the plasma interact with any surface with which they are in contact.

Plasmas produced from oxygen gas are efficient and environmentally safe for critical cleaning. The various oxygen species created in the plasma (e.g. O_2^+ , O_2^- , O_3 , O , O^+ , O^- , ionized ozone, excited oxygen, and free electrons) assist cleaning. They react with organic contaminants to form H_2O , CO , and CO_2 , and lower the

molecular weight of the hydrocarbons. While these activated oxygens react with organic contaminants to form volatile compounds, the glass surface is chemically modified by oxygen addition and loss of components such as alkalis.

In addition, the vacuum UV energy is effective in breaking most organic surface-contaminant bonds, dissociating high-molecular weight contaminants and creating volatile compounds. The contributions of the individual processes depend on various electrical and geometrical parameters and discharge conditions. The most important parameters in glow-discharge cleaning are the applied voltage, the current density, type of gas and gas pressure, duration of treatment, type of glass to be cleaned, and shape and arrangement of the electrodes. Owing to particle bombardment and surface interactions of ions and electrons, the transfer of energy to the substrate causes its temperature to increase up to 200 °C, which favor further the desorption of adsorbed water and some organic contaminants.

Substrate cleaning in high vacuum by ion bombardment generated in special ion sources is rarely used in industry. Ion-beam technologies offer interesting opportunities, however, not only for cleaning but also for the polishing and machining of optical surfaces, for structuring, and for modifying the optical constants of the glass surface in regions that may be of interest for making micro-optics and integrated optical devices.

In summary, surface cleaning is performed by various methods, such as washing with solvents, heating, UV, and plasma treatment. Each has its specific domain of applications. Solvent cleaning has the greatest range of utility but is inadequate in many cases, particularly when the solvents themselves are contaminants. Heating is useful only up to a maximum temperature so that plasma treatment represents a valuable method when contaminants are so strongly bonded that higher temperature would be needed to eliminate them because the plasma energy can be much higher than achieved thermally without damaging surfaces, thanks to its low flux.

4 Strengthening

4.1 Ion Exchange Processes

Two common technologies to improve mechanical properties rely on the stress generated in the glass surface region by ion exchange and thermal treatment. Referring to Chapter 3.12 for detailed presentations, it will suffice here to recall that, by dipping a preheated float glass sheet into a tank of molten KNO_3 below the strain point for several hours, one substitutes small

Na^+ ions by larger K^+ ions and creates in this way compressive stresses near the surface large enough to increase the glass strength by a factor of 3–5. Although discovered many years ago [19], the process failed to penetrate large markets until the advent of chemically strengthened flat aluminosilicate glasses such as Corning® Gorilla® Glass, Schott Xensation™, or Asahi Dragontrail™, which have become high-value keystone components in displays and handheld electronic devices (Chapter 6.10), solar cell covers (Chapter 9.4), and, increasingly, automotive glazing (Chapter 9.2) in addition to gradient index lenses and waveguides. For reasons of cost, throughput, and specific technical challenges, however, today's applications are still limited to small-area glasses although the process has the advantage of being applicable to curved or thin glass articles.

4.2 Thermal Tempering

In glass production, temperature plays a crucial role not only upon melting but also on cooling and during post-treatment procedures. The most commonly used process for thermal tempering requires uniform heating to approximately 600–650 °C followed by a rapid cooling by air blown uniformly onto both surfaces simultaneously. Quenching creates near the surface a high compression over approximately 20% of the glass thickness whereas the central core finds itself under tension. Under uniform loading, heat-treated glass is stronger than annealed glass of the same size and thickness. Depending on the degree of residual surface compression or edge compression, heat-treated glass are said to be heat-strengthened or fully tempered. The higher compression levels can create products that are generally stronger than annealed glass and twice as strong as heat-strengthened glass of the same thickness and type. As the compression levels increase, the size of the fragments of broken glass tends to become smaller.

With the exception of strength and breakage characteristics, these glasses retain the normal properties of annealed glass, including chemical resistance, hardness, expansion, and optical characteristics. Heat-treated and tempered glasses have been produced for the architectural market for more than 30 years, being now surpassed in volume only by annealed glass. Today, products are available for architectural (Chapter 9.1) as well as for residential and for automotive applications (Chapter 9.2). They are also called *safety* glasses since tempered pieces break into small fragments, which are less of a hazard than the large and sharp pieces resulting from a broken lite of annealed glass.

5 Modification of the Surface Topography

5.1 Process and Surface Topography

The topography of a glass surface strongly influences features ranging from light scattering to chemical reactivity. When thin films are deposited, their adherence and microstructure in addition depends on their interactions with the surface and its topography, which is generally not perfect and homogeneous at a microscopic scale. Depending on the length scale, it is useful to distinguish between *flatness* in the cm range or more, *waviness* at the scale of the wavelength of light, and *roughness* in the nm range.

The topography is determined by both the production process and glass composition. In general, all glasses shaped by pressing, drawing, or rolling show characteristic marks that often replicate the surface of the tools with which they were in contact. Thanks to the preservation of the originally smooth interface of the liquid, such features are not present in flame-polished surfaces produced by usual blowing techniques and the float process. Likewise, a low surface roughness in the nm range is achieved by other forming processes when there is no direct contact with the soft molten phase. For example, most drawn glasses have smooth surfaces with occasional surface irregularities of approximately 100 nm in height. But drawn borosilicate glass tends to be wavy because of its relatively high drawing temperature and short working range.

5.2 Grinding and Polishing

For simply shaped surface contours, hot pressing and molding of glass are used without further surface finishing operations to produce, for example, mirror substrates for various small projector lamps, signal lamps, or automobile reflectors. More complex and accurate surface shapes of high-quality products, like glasses for optics, electronics, space technology, and biomedical applications, are produced in curve-generating machines by milling and lapping operations. Different operational steps are then required with increasingly finer grinding grains to achieve a finish suitable for starting the polishing process.

The grinding process is dominated by physical effort. Small glass fragments are removed when they break out under the action of loose or bound abrasive grains (silicon carbide, electro corundum, or diamond) tied to iron or brass discs, which are harder than the glass itself and have a size that determines the particle size broken out upon grinding. The combined effect of the load of the abrasive particles and the additional tensile stress in the surface that results from their frictional pull cause breaking and flaw formation. The pressure of the shaping tool

on the surface and the relative speed between tool and glass are directly proportional to the weight removed. Water is used both as a cooling medium and an agent distributing evenly the grinding grains.

After grinding, polishing serves to produce homogeneous and optically highly transparent surfaces with a low roughness, be they extremely flat, spherical, aspherical, or of a complex shape. Metal oxides (ZrO_2 , Fe_2O_3 , CeO_2 , AlO_3 , etc.) on cloth or pitch polishers are applied to smoothen the surface in the presence of water. Polishing theories are roughly classified into three groups [3]: (i) in the *wear* theory, polishing is an extension of grinding involving the mechanical removal of asperities; (ii) in the *flow* theory, asperities flow plastically into surface cavities under the pressure exerted or upon frictional heating; (iii) in the *chemical* theory, the asperities are removed by transformation into compounds produced in chemical reactions with the polishing agents that can then be easily removed mechanically. Combining such physical and chemical effects, the main parameters affecting the polishing process are not only the glass type and the surface state after grinding but also its speed, pressure, and kind of materials and compounds used.

There are various ways to polish glass surfaces. In technical applications, polishing requires at least two steps. First, the ground gray surface is smoothed by the action of the oxide/water slurry and a silica gel is produced as a reaction product of glass and the polishing agents, which smears and glazes the smoothed surface areas and fills the remaining cavities. The created surfaces are rather smooth but have high waviness. In the second step, the conditions are adjusted to favor smearing and enhance polishing. The latter is important to remove the last remaining cavities. At the end of the process, the remaining polished layer consists mainly of silica gel and, therefore, differs appreciably from the bulk glass.

For high-quality optical glass surfaces, ion figuring is applied. This is a complementary, non-contact technology to avoid or eliminate problems associated with traditional contact polishing. The process is based on bombardment by particles of an inert gas, which results in soft sputtering of the substrate material. The technique is an excellent tool for contour corrections or for ablating the water-rich polishing layer. It does not improve the surface smoothness, however, and can expose subsurface damage on less carefully, traditionally polished samples.

6 Structuring and Texturing

More and more modern applications need specific structures in the surface region. For structuring and texturing in the nm to μm range, various approaches are applied in

industry and many more are under development. Traditionally, molding or embossing techniques have been used for the fabrication of patterned surfaces based on the viscous deformation at temperatures close to the glass transition temperature T_g (Figure 7).

In the cold state, wet chemical etching with hydrofluoric acid and also sandblasting are common to obtain frosted or matted surfaces. Now, CO_2 lasers producing infrared radiation ($10.6\ \mu\text{m}$) are used to structure glass whereas laser-etching techniques combined with wet etching are being evaluated and novel atmospheric-pressure plasma-assisted laser ablations are under investigation. More sophisticated processes are also being applied to structure glass surfaces, such as electron-beam, laser interference lithography, or reactive-ion etch process with gas mixtures of CF_4 and O_2 . In particular, more advanced glass applications in which glass is used in combination with silicon, such as PVs or MEMS, created a demand on new structuring technologies.

For example, aluminum-induced texturing (AIT) is a promising and potentially low-cost method [21–23]. As indicated by a schematic process flow (Figure 8), a thin metallic Al film deposited on the glass surface is annealed at high temperatures in an inert atmosphere to initiate a redox reaction at the interface ($4\ \text{Al} + 3\ \text{SiO}_2 \rightarrow 3\ \text{Si} + 2\ \text{Al}_2\text{O}_3$). Removing the reactants by wet-chemical etching, one obtains a textured glass surface made up of c-Si clusters surrounded by Al_2O_3 crater-shaped nodules embedded into the glass, with a width and a depth of about 5 and 1 μm , respectively [24]. The surface texture depends on the nucleation conditions during annealing. With AIT (Figure 9), the total reflectance of the glass surface is 1–2% lower than that of the bare glass and has a significantly higher diffuse reflectance.

Such advanced surface structuring technologies open new application areas for glass. Complex surface decors or large-area surface structuring on architectural glass can be realized. For example, antireflective (AR) surface structures and coatings are needed for most existing optical components and optoelectronic devices, ranging from solar cells (Chapter 9.4), photo detectors, light-emitting diodes (LEDs; Chapter 6.9), and laser diodes. Photovoltaic cover glasses can contribute to the overall energy conversion efficiency of photovoltaic devices by improving the illumination of the converter. Patterned cover glass surfaces are one solution. Other solutions include prismatic microstructures, moth-eye surfaces, or sub-micrometer diffraction gratings applied to trap light by multiple reflections and to guide selectively the incoming sunlight.

High-precision surface microfabrication of optically transparent materials is crucial too, to structure the microfluidic channels used in lab-on-a-chip and micro total analysis systems ($\mu\text{-TAS}$), as well as for micro-optics

in photonics. Special micro-structured glass surfaces are needed for micro-mechanical, micro-fluidic, and micro-optical MEMS devices. Micro-lenses and micro-lens arrays are increasingly used for coupling in multi-fiber connectors, as collimators for LEDs and high-power laser bars. Micro-lens arrays are being implemented in wavefront sensors, pixel-based CCD cameras, confocal microscopy, and direct optical one-to-one imaging. Movable micro-optic elements for beam deflection and modulation in scanners and switches have also been reported.

In the R&D-pipelines are novel concepts and methods to make nanostructured glass surfaces for controlling the functionality of materials at the interface of applications in biology, medicine, and energy. These studies will have a large input on existing technologies.

7 Applications

Applications of the glass material have kept diversifying for about four millennia. In many traditional products such as containers or tableware, glass is preferred for obvious reasons but its surface is not a critical factor. Whereas markets for such commodity products are stable, most surface treatments are realized at the hot end of production line with the exception of thick-film technologies used for decoration. In other traditional uses such as glazing, the float-glass surface is modified to provide applications not imagined a few decades ago. In newer glass applications, concerning, for instance, information or energy technologies, glass has increasingly become an enabling component whose importance is ensured by special surface features. In some cases, the glass may be unrecognizable in the final product – but the product cannot be made without it.

A paradigm shift thus seems now underway because of “seismic” changes driven, for example, by environmental factors, a rapidly changing energy market, or advances in the biomedical field. In all these instances (Figure 10), new functionalities are or have already been developed [26] through either surface treatment or thin-film deposition (Chapter 6.8). In other words, the more advanced the product and the more important has become its surface. Traditionally, the glass surface has been perceived as ensuring chemical durability as exemplified by the dishwasher resistance of tableware. Visible corrosion was correlated with poor glass properties, which is why the chemical resistivity is used for classifying packaging materials. But R&D activities in very different sectors have changed this simplified view. More attention is now directed to glass surfaces. The need to improve glass strength to reduce weight, or to nanostructure glass

Figure 7 White-light interferometry image of a patterned glass surface [20].

Figure 8 Process flow of the aluminum-induced texturing method.

surfaces for optoelectronic and micro-optics, and research on glass surfaces for biomedical applications have contributed to this paradigm shift.

8 Perspectives

Most advanced and future glass applications are based on very specific functionalities of the surfaces, i.e. surface technologies have become key enablers. A broad

Figure 9 Atomic-force micrograph of a textured glass surface after the aluminum-induced texturing process [25].

spectrum of techniques is thus already applied and others are under development to address very different topics from roughness on the atomic scale to structured surfaces and durability in various media. Applications range from large-area glass sheets for architecture to small pieces for micro-optics. Since most, if not all, relevant glass properties ultimately depend on surface properties, these technologies will have key functions in the fabrication of glass products with novel attributes. Surface treatments (Chapters 6.8 and 8.2) will be key technologies for many future applications by providing new solutions to satisfy market demands. Existing and future applications (Figure 10) with special surface properties (and coatings) are so numerous that only a few will be mentioned in electronics, pharmaceutical packaging, and biomedicine.

Thin and ultra-thin, bendable, flexible glasses are desired for various applications, for instance, to save weight in information technology (IT) and transport systems. Displays and electronics are becoming lighter, thinner, and more flexible so that the choice of substrate continues to be critical to their overall optimization since it directly influences improvements in the design, materials, fabrication processes, and performance (Chapter 6.10). Thin and *unbreakable* glasses seem to be the “holy grail” of glass scientists in the twenty-first century. The intrinsic mechanical strength of thin glasses is already good but there remains room to reduce surface defects and the

Figure 10 Application fields of modified glass surfaces: present situation and most relevant markets.

ubiquitous presence of damage caused by mechanical or thermal shock, compounded by interactions with the environment. Although glass strength is an application-dependent issue, one can enhance it in three different extrinsic ways, namely, by polishing and chemical etching to achieve a high-quality surface finish, by inducing surface compressive stresses through thermal or chemical tempering, and by coating to protect the surface.

Glass substrates enable high-quality, long-life devices, thanks to their inherent advantages such as surface quality, optical transmission, hermeticity, and thermal and dimensional stability, which are kept when the substrate thickness is reduced below 200 μm in high-performance flexible electronics. In addition, a reduction in thickness allows new device designs and high-throughput, continuous manufacturing by roll-to-roll processes (Chapter 6.10). For glass optics in high fluence and high-peak power lasers, surface quality affects dramatically the laser damage resistance so that structured glass surfaces will become more important in photonics. Future activities on nano- and micro-structured surfaces include the making of hollow-core photonic crystal fiber (PCF) from glass. New fiber lasers and sensors will be realized, optical fiber quality will improve, and nano-gratings will be formed on their surface. Other areas needing structured glass surfaces include micro-fluidics used in the lab-on-a-chip and μ -TAS.

Other examples for “new” glass surfaces come from the biopharma field where proteins, peptides, or living-cell formulations may interact with the currently available packaging more extensively than “classical” drug formulations or via different pathways. Additional topics of increasing significance arise from safety considerations (cytostatics, living cells, genetically manipulated organisms, etc.). These aspects have the consequences that future glass packaging for drugs will require surfaces with an extremely low potential for interactions with their contents and should be unbreakable (Chapter 7.7).

Many activities in cellular nanotechnology aim at making biological interfaces smarter. Engineered cell–material interfaces are generated for fundamental cellular studies, tissue engineering, and regenerative medicine. Aspects of nanostructured interfaces – nanotopographical control, dynamic behavior, and intracellular manipulation and sensing – have been investigated to understand cell function and provide new ways to control cell activity. The surfaces of bioactive glass scaffolds are also of interest, since they have the potential to match the engineering design criteria for bone regeneration when foamed to produce scaffolds that mimic cancellous bone macrostructure (Chapter 8.4). The surfaces of macropore networks are important for cell migration, bone ingrowth, and blood vessel penetration. Bioactive glasses in body fluid react to form a bone-like mineral layer on the

surface and also release soluble silica and calcium ions that stimulate cells to produce new bone.

Thin-Film Technologies for Glass Surfaces

Sener Oktik¹, İlkey Sökmen¹, and Klaus Bange²

² MK Consulting GmbH, Jugenheim, Germany

1 Introduction

In the past, the special optical properties of glass have been at the roots of many technological advances. As early illustrated by the first attempts made to improve reflectivity, however, these properties had to be adjusted to make specific applications possible. As an example, the making of glass mirrors relied on the use of mercury layers, which was known by about 1369 shortly before thin amalgam films became available. As for the colors produced from light diffraction by thin films, they have fascinated observers throughout the ages; a most vivid description was made by Newton in his *Opticks* where he went far beyond a simple qualitative description of the phenomenon [1]. Later, significant enhancement of glass reflectivity was achieved with highly reflecting metal films. For instance, mirrors with silver films deposited by wet chemical processes were produced in 1835 [2, 3], well before attempts were made to deposit films on mirror surfaces by evaporation and condensation of various metals under vacuum in 1912 by Pohl and Pringsheim [4].

The first antireflection layer, for lower reflectivity applications, was deposited accidentally on glass in 1817 by von Fraunhofer [5, 6] in Germany, who recognized the unusual properties of a thin film of low refractive index when treating polished glass with concentrated sulfuric or nitric acid, but no technical application followed at that time. Much later, Strong [7] in the United States and Smakula [8] in Germany developed in the mid-1930s single-layer antireflection coatings by evaporating and condensing calcium fluoride (CaF₂) under vacuum onto glass surfaces. In 1938, Cartwright and Turner [9] suggested further suitable compounds such as magnesium fluoride

(MgF₂) and cryolite (Na₃AlF₆). Attempts to develop multilayer antireflection coatings had already been made at that time in the United States [10]. At Schott and Genossen in Germany, Geffcken [11] deposited in 1939 dielectric metal thin-films to produce a narrow-band interference filter of the Fabry–Perot type. But the practical realization of environmentally stable, complex thin-film interference systems required hard and resistant coating materials. Multilayer antireflection coatings, various interference mirror stacks, beam splitters or high- and low-pass edge filters became available in 1950 in the form of various oxide films deposited by reactive deposition. From then on thin-film materials and systems have been extensively developed alongside the conception and detailed development of both computer-aided coating design and coating production methods.

Thin films now underpin numerous applications by adding a variety of functionalities to surfaces that can be hydrophilic or hydrophobic, oleo-phobic, antifogging, slippery (lubricant), self-cleaning, easy-to-clean, anti-fingerprint, photo-catalytic, antimicrobial, antibacterial, antithrombotic or can prevent bio-adhesion, bio-films, or crusting of blood. In addition to optical properties such as transmittance, reflectance, absorbance, and color, the electrical, mechanical, or chemical properties of glass thus strongly depend on surface conditions, which is why they can be optimized by means of deposited thin films. For example, glass is known to be a good electrical insulator. For the most advanced application in information technology or in the photovoltaic sector, however, such a good electrical conductivity must be combined with a high transmittance. Thin transparent and conductive films are available today but also very thin, nearly invisible, metal bars, and electrodes have been used for decades. Likewise, the high chemical durability of glasses against acids, alkalis, staining, water, or weathering as

assessed by durability tests (Chapter 5.1) can be improved with special coatings (Chapter 7.7). Improved scratch and abrasion resistance, corrosion protection, and an ability to act as a (gas) barrier or release system have also been engineered.

Today, coated glasses with low-emissivity (low-e) layers are the most popular products, in particular in the architectural and automotive fields. Besides those coatings, multiple layer systems on glass have been studied for more than two decades to create active or passive devices, which can change the light or heat transmission and emission properties by application of a voltage. However, only in recent years have these *smart-glass technologies* been transferred to large-volume productions and become available on the market. They have given rise to new and innovative applications and functionalities, increasing efficiency and reliability, and even decreasing costs.

This chapter thus describes the principles of manipulating glass surface properties through deposition of thin films and summarizes the most relevant deposition techniques used. It identifies the most important properties that can be modified by addition of thin films and discusses the influence of their composition, thickness, and density. The properties of technical and commercially relevant thin films and film systems on glass, such as indium-tin oxides, low-e, and antireflection coatings will be explained and several glass properties will be stressed which can be modified.

2 Deposition Techniques

The term *vapor deposition* refers to any process by which a thin film is deposited on the surface of a solid by transfer of material from the vapor (Figure 1); since the vapor is created by purely physical means, the process is called physical vapor deposition (PVD). In PVD, the production of atoms/ions/molecule species in a vapor from a solid or molten source is followed by their transfer onto the substrate in vacuum. The material may be evaporated from thermally heated sources or from sources heated by a high-energy electron beam in a chamber (thermal evaporation) or physically ejected from a solid target surface by momentum transfer of high-energy gaseous ions accelerated from a plasma (sputter deposition). Alternatively, a high-current, low-voltage arc is employed to vaporize a cathodic electrode (cathodic arc) or an anodic electrode (anodic arc) and the vaporized ions are accelerated toward a biased substrate (arc vapor deposition) or a high-power pulsed laser beam is focused to a target and the evaporated material moves in a plasma plume (pulsed laser deposition [PLD]).

Figure 1 Overview of the most common physical and chemical processes for thin-film deposition on glass surfaces.

In chemical deposition methods, in contrast, the vapor is created through a chemical reaction either in a gas phase or in a solution. Although the former case of chemical vapor deposition (CVD) is the most important, spray pyrolysis and sol-gel methods such as dip-coating are solution-based processes that are also often used (Chapter 8.2). The three major steps in a typical thin-film CVD or PVD process are (i) the production of the appropriate atomic, molecular, or ionic species in the vapor; (ii) the transport of these species to the substrate through a vacuum; and (iii) the condensation on the glass substrate, either directly or via a chemical reaction, to form a solid deposit.

The unit vapor species impact on the glass substrate and transfer energy to it; they are adsorbed if the incident energy is not too high. These mobile adsorbed species, which are not initially in thermal equilibrium with the substrate, can interact among themselves to form bigger clusters. Depending on the deposition conditions, these thermodynamically unstable small clusters (also called nuclei, Chapter 5.4) either desorb over time or capture other adsorbed species to grow in size. After reaching a critical size, the cluster becomes thermodynamically stable. The number and size of the nuclei grow until a saturation nucleation density is reached, which depends on the energy and number of striking species, the activation energies of adsorption, desorption, thermal diffusion, and the temperature, topography, and chemical nature of the substrate. Usually at this stage the lateral rate of nucleus growth is much higher than the perpendicular

growth rate. The grown nuclei are called islands. Small islands agglomerate to reduce the substrate surface area at a rate that one can accelerate by increasing the surface mobility of the adsorbed species, for instance, by raising the substrate temperature. Larger islands finally coalesce, leaving channels and holes where the substrate is bare. The film structure changes from discontinuous-island to porous-network type while the channels and holes are filled to yield a completely continuous film.

In summary, the successive steps of film growth, namely nucleation, surface-diffusion, two- or three-dimensional nucleation, formation of a network structure, and subsequent filling of holes, result in a continuous thin film. Various growth stages are observed and different growth models apply depending on substrate surface, coverage, film material, and deposition process and conditions. In a simplified categorization, the initial stages (Figure 2) distinguish between the 3-D morphology of island growth (Volmer and Weber [12]), the 2-D morphology of layer-by-layer or step-flow growth (Frank and Van der Merwe [13]), and the two-step layer-plus-island growth whereby a 3-D morphology develops once a 2-D film has reached a critical thickness (Stranski and Krastanov [14]). In almost all practical cases, the island type is the most common process but in polycrystalline thin films and under special conditions other types are observed too.

With increasing thickness, the film acquires its final structure as mainly determined by diffusion at the surface and in the bulk of the film, recrystallization and

Figure 2 Cross-sections of models of the initial modes of thin-film growth for different surface coverages: island formation (Volmer–Weber), layer-by-layer (Frank–van der Merwe), and layer-plus-island (Stranski–Krastanov) growth.

shadowing effects, which all depend on the substrate temperatures T_s [15]. The growing film develops a local and longer-range structure relative to the substrate, which can be amorphous or polycrystalline and often shows preferred orientation and columnar growth, termed growth texture. Textures influence the film properties through the orientation-dependence of the refractive index or mechanical stress. Concepts to explain differences in such an oriented growth through the so-called structure zone models have been introduced in terms of the ratio between the melting temperature T_m of the film material and the substrate temperature [10]. Structure zone models have also been deduced for sputtered films and for ion-assisted deposition (IAD) [10, 15]. Additionally, the influence of substrate morphology has also been taken into consideration [10, 15, 16].

CVD (and derivative methods such as spray pyrolysis) is the technique used today to deposit coatings *online*, i.e. directly on float-glass lines whose production amounts to several hundred tons per day. Of particular importance thus is the capacity to deposit at high temperatures a wide range of elements at high rates with an excellent adhesion to the substrate. As a matter of fact, online coating deposition is a proven way to manufacture low-cost and durable products from float glass for automotive and architecture.

Another well-established method for manufacturing a wide range of thin films on flat glass is *offline magnetron sputtering*. In the past, glass was sputter-coated after being cut and tempered, usually in its final shape; today, process and material development have allowed this production chain sequence to be changed. In sputtering, the coating species is formed as the recoil product of the collision of a heavy ion with a target of the coating material. The principal advantages of sputtering are the ability to deposit under controlled vacuum conditions either pure metals or metal compounds (nitrides, oxides, etc.) along with the ready availability of highly pure metal targets and various reactant gases. In addition, the possibility of flexible multilayer design allows the optical performance to be optimized as exemplified by thin multilayer systems that can control UV and IR radiation.

3 Thin Films

3.1 Thin Film Materials on Glass and Film Properties

Thin film structures can be engineered today at the atomic level as a result of multidisciplinary research and developments in the fields of vacuum science, solid-state physics and chemistry, surface science, crystal growth, statistical/computational physics, and

characterization methods. The new properties have become the basis of advanced technologies, devices, and industries. The peculiar properties of thin-films of course determine the achievable performance of manufactured products. Although the layers usually consist of well-characterized materials, their properties differ from those in the bulk for three main reasons: (i) these layers are not grown under thermodynamic equilibrium, for example, when the substrate temperature is low or when bombardment energies are high as is the case of IAD techniques; (ii) the high surface-to-volume ratio dramatically changes the physical properties and chemical characteristics; (iii) the optical properties are in addition influenced by the substrate surface and interface morphology. All these quantities are strongly affected by the film preparation method, the chosen parameters, and post-deposition treatments.

Deposition processes depend on a number of parameters that can be varied over broad ranges to ensure predefined physical properties. For PVD processes, these are the deposition rate, the temperature of the glass substrate during deposition or post-deposition annealing, the total gas pressure and partial pressures of the remaining gases and dopant gases in reactive processing, the energy of the deposited particles and bombarding gases, etc.

Thin-film materials for glass coatings are in general grouped into two main categories, namely dielectrics and metals, alloys, semiconductors, and carbon. Dielectrics present an excellent match with the optical performance of glass so that they are preferentially applied as optical coatings. Standard industrial thin-film materials are thus oxides, oxynitrides (e.g. SiO_xN_y), nitrides (Si_3N_4), and carbides (SiC). Oxides such as SiO_2 , Al_2O_3 , HfO_2 , Y_2O_3 , ZrO_2 , Ta_2O_5 , Nb_2O_5 , TiO_2 , ITO (indium-tin oxide), or ZnO are favored because they offer a broad variety of refractive indices and wide spectral ranges of high transmission. Additional advantages are their hardness, abrasion-resistance, and chemical and environmental stability. One may in addition tailor the refractive indices of these films by appropriate oxide mixing. As for SiO_2 films, they have excellent barrier properties, blocking not only the in-diffusion of gases and water but also alkali leaching from the glass [10, 16].

Oxide films are also widely used in multilayer systems. Owing to large differences in refractive indices, the combination of highly refractive TiO_2 with low-index SiO_2 films is commonly used as an efficient broadband reflector in TiO_2 – SiO_2 quarterwave-stack multilayer systems. For multilayer systems with higher accuracy, thermal stability, and lower optical losses, TiO_2 is sometimes replaced by tantalum oxide. Like hafnium oxide, Ta_2O_5 is also a good high-index material for multilayer systems used in the UV spectral region. These materials are often applied for special films in optical applications such as

cold-light mirrors, heat-reflecting filters, color separators, narrow-band interference filters (e.g. dense wavelength division multiplex filters), and laser-optics coatings. To tailor refractive indices, mixtures of oxides are deposited too.

Fluorides (AlF_3 , BaF_2 , CaF_2 , Na_3AlF_6 , DyF_3 , GdF_3 , LaF_3 , MgF_2 , NdF_3 , TbF_3 , and YbF_3) are another class of dielectric thin-film materials used for special UV coatings. Applications at wavelengths below 200 nm are possible because several fluorides have bandgap energies around 10 eV. The materials of choice are magnesium fluoride (MgF_2) and lanthanum fluoride (LaF_3) for low and high refractive-index layers, respectively. Mainly for IR applications, but also for electro-optical devices, sulfide, selenide, and telluride thin films are otherwise of interest (Sb_2S_3 , Sb_2Se_3 , ZnS , ZnSe , ZnTe , CdS , CdSe , CdTe , and PbTe).

Extensive information is needed to characterize adequately thin films, in particular for use in multilayer systems. Since films can have thicknesses in the low nm range and offer little material for analysis, correct basic data for coating materials are difficult to be obtained as analytical methods must be very (surface) sensitive to give reliable results [10]. Macroscopic properties include thickness, refractive index, absorption, light scattering, adhesion to the substrate, stress, density, homogeneity, and hardness; microscopic quantities refer to composition and chemical binding state of elements, stoichiometry, impurities, topography, roughness of surface and interface, formation of interfaces, crystalline or amorphous state, and also the structure of crystals and the local order of noncrystalline materials.

3.2 The Example of TiO_2

Among the great many techniques and materials available to produce the desired optical, mechanical, and chemical film properties, in practice, the choice is determined by specific film requirements. Here, TiO_2 thin films will be used to illustrate such complex interrelations between the properties of the films deposited and the deposition conditions and techniques used. The high refractive index of TiO_2 makes it one of the most important in thin-film materials. It is of interest to commercial products as different as specific interference filters and mass-produced anti-reflecting coatings for shop windows. Now the refractive index of TiO_2 films prepared by different deposition techniques can, for instance, vary by 0.4, a difference that of course influences product performance. These films may in fact contain various foreign elements introduced either intentionally as dopants to adjust properties or, more often, as undesired impurities at various concentrations, in both cases influencing other features such as the crystallization tendency. These impurity

contents are very specific to the deposition process used. In general, they originate from the solutions used in CVD or in the reactive gases and targets in PVD, thus giving valuable information for reverse engineering.

Chemical analyses of the composition do exhibit deviations from the ideal TiO_2 stoichiometry. Compositions of $\text{TiO}_{2.04}\text{Ar}_{0.05}\text{Ta}_{0.003}\text{H}_{0.05}$ and $\text{TiO}_{1.9}\text{Cl}_{0.08}\text{Na}_{0.5}\text{Ca}_{0.01}\text{H}_{0.04}$ have, for instance, been determined for films deposited by sputtering and by sol-gel processes from combined nuclear reaction analyses and Rutherford backscattering spectroscopy [10]. Such data demonstrate that it is meaningless to “know” film properties without careful analyses and an in-depth understanding of the deposition process.

In addition to composition, a core property, another vital parameter is density, which influences many film properties like crystallinity, layer stress, and refractive index (Figure 3). Powerful analytical techniques, such as grazing incidence X-ray reflectometry and Rutherford backscattering spectroscopy are now available to quantify it to high accuracy. Often the density is reported relative to that of a crystalline phase, $\rho_r = \rho_{\text{film}}/\rho_{\text{cryst}}$. With anatase ($\rho_{\text{cryst}} = 3.84 \text{ g/cm}^3$) as a reference for TiO_2 films, one finds that ρ_r , for example, increases from 0.7 for films deposited by dip coating in sol-gel processes (Chapter 8.2) to 1.0 for others made with some advanced PVD and CVD techniques (Figure 4). The densities for other deposition techniques lay between these two extremes although values higher than 1 have even been reported [17, 18].

Most TiO_2 films are amorphous under X-rays but the TiO_2 polymorphs anatase, rutile, and brookite have been observed on float-glass substrates. An increased Na concentration in TiO_2 films, by diffusion from the glass substrate, is essential for the precipitation of anatase and brookite [10, 15]. The onset temperature for crystallization correlates with composition and density. In films of higher density, the formation of dense rutile is favored, which can induce defects [17, 18]. As may be expected, density is to a first approximation directly proportional to the refractive index n and decreasing H (H_2O , OH) content in the film, and also correlates with a change from tensile to compressive stress (allegedly $>1000 \text{ MPa}$ for some PVD films), see Figure 4.

4 Transparent Conducting Oxides

4.1 General Remarks

The two main applications of transparent conducting oxides (TCOs) are the thin films used (i) as electrodes in optically and electrically active systems such as liquid-crystal and organic light-emitting diodes (OLED) flat

Figure 3 Anatase (TiO_2) thin films deposited at 200°C on float-glass surface as examined by transmission electron microscopy. Small crystal sizes and low densities achieved with (a) sol-gel process and (b) reactive evaporation. Larger crystals and higher densities obtained by (c) ion-assisted deposition and (d) chemical vapor deposition followed by 500°C annealing.

Figure 4 Density ranges of TiO_2 thin films deposited by traditional (sol gel, evaporation) and more advanced (CVD, ion-assisted deposition) techniques and the associated tensile or compressive nature of their internal stresses [17].

panel displays, photovoltaic cells, electrochromic devices, touch screens, etc. (Chapters 6.9 and 6.10) for which ITO is the current industrial standard material; and (ii) for windows in buildings and transportation vehicles to improve thermal insulation, heat preservation, and sun management. Whereas a high electrical conductivity is most important as an enabler for many high-tech products in the first series of applications, the optical properties in the NIR are more relevant in the second.

For very different applications a frequently used thin-film material is SnO_2 . While still hot, newly shaped bottles get, for example, their surface protected by a very thin SnO_2 layer deposited with a CVD process relying on SnCl_4 as a starting material (Chapter 1.5). Likewise, pyrolytic CVD is used online at the float plant to deposit fluorinated tin oxide ($\text{SnO}_2\text{:F}$) at high temperatures to improve the insulating properties of the glass. Besides CVD there are several ways to grow SnO_2 (either doped or un-doped) films on glass, including PLD, DC reactive sputtering, and spray pyrolysis.

4.2 Optoelectronics

Indium oxide doped with Sn (ITO) or Zn, tin oxide doped with F or Sb, and zinc oxide doped with Al, B, or Ga have

the special interest of being electrically conducting substances with a high optical transmission in the visible range. Charge carriers are interstitial metal-ion impurities, oxygen vacancies, and doping ions. Most TCOs are n-type semiconductors where defect/dopant donates electrons to the conduction band, providing charge carriers for the flow of an electric current; p-type TCO materials have also been reported where the defects act as electron acceptors.

For a film of uniform thickness t and resistivity ρ , the sheet resistance R_s can be expressed as $R_s = \rho/t$. For a semiconductor, the resistivity depends on the charge carrier density N and carrier mobility μ as given by the relation $1/\rho = N\mu e$, where e is the electron charge (1.602×10^{-19} C). If N is increased to reduce ρ , the TCO film transmission, especially in the near infrared (NIR), is also reduced because of free-carrier absorption and metal-like reflection so that lowering the TCO resistivity ρ by increasing N adversely lowers the near IR optical transparency of the film. In contrast, increasing the carrier mobility decreases ρ without reducing the NIR transmission.

The effort made to optimize TCO thin-film preparation in recent decades has resulted in leveling off of resistivities at 10^{-4} Ω cm. The most practical materials applied today, the so-called *heavily doped wide bandgap semiconductors* are $\text{In}_2\text{O}_3:\text{Sn}$ (ITO), $\text{SnO}_2:\text{F}$ (FTO), $\text{ZnO}:\text{Al}$ (AZO), and $\text{ZnO}:\text{Ga}$ (GZO). All films have a high transmittance in the visible range, a high infrared reflectance, and a resistivity $\sim 10^{-4}$ Ω cm for thicknesses near 200 nm.

Currently, the industry standard in TCO films is ITO, or tin-doped indium oxide (typically 90% In_2O_3 , 10% SnO_2 by weight), which is used in many electro-optical devices (Chapters 6.9 and 6.10). This heavily doped n-type semiconductor has a large bandgap near 4 eV and is transparent for most visible wavelengths (Figure 5). It is in contrast opaque in the UV (where photons can excite electrons across the bandgap in *band-to-band* absorption) and also in the NIR (where IR photons can excite electrons from near the bottom of the conduction band to higher levels within the same band in *free-carrier* absorption). Ranging from amorphous to crystalline, the structures of the ternary compound ITOs are determined by the deposition conditions prior to the post-process thermal annealing steps applied.

These thin films are deposited mainly by magnetron sputtering (MS) technologies known as direct-current MS (DCMS), pulsed DC MS (PDCMS), high-power pulse MS (HPPMS), and radio-frequency MS (RFMS). Other processes used are ion-assisted plasma evaporation, (low temperature) electron beam evaporation, thermal evaporation, or PLD. Today, deposition on large areas of float-glass sheets is carried out at high rates and moderate processing temperatures; the films exhibit a high optical uniformity and a low resistivity. Since indium is

Figure 5 Spectral transmission and reflectance of indium-tin oxide films (thickness: 273 nm; sheet resistance: 16 Ω/sq) on soda-lime glass (Sişecam Science and Technology Center Internal Report 2017).

a rare and expensive metal, the main drawback of ITOs is their cost.

Finally, applications of TCOs to solar-cell technology must also be mentioned. They rely on tin oxide (SnO_2), a wide bandgap semiconductor ($E_g > 3$ eV) that exhibits an optical transparency higher than 85% and has an n-type character conferred by oxygen vacancies. Its electrical conductivity can be significantly enhanced by foreign dopants. The most favored are antimony replacing tin and fluorine substituting for oxygen. The hybrid orbital configurations $2s^2 2p^5$ and $2s^2 2p^4$ for F and O, respectively, suggest that F atoms donate one free electron/molecule when F replaces O. The ionic radius of F^- (1.36 Å) is slightly smaller than that of O^{2-} (1.40 Å), which makes this substitution easy. Actually, F-doped SnO_2 exhibits a good transparency in the visible, owing to its wide bandgap, while retaining a low electrical resistivity due to the high carrier concentration caused by the O vacancies and the substitutional F dopant. Because fluorine-doped transparent oxides are mechanically, chemically, and electrochemically stable, they are used to enhance the efficiency of solar cells as dielectric layers in low-e coatings for windows. Another, unrelated application is in gas sensors which can be divided into two main groups: the first includes sensors that detect oxygen with variations of bulk or surface conductance; the second comprises materials that detect oxidizing and reducing gases in air at constant oxygen partial pressure.

Figure 6 Decrease of light transmission with an increasing number of Ag layers in low-emissivity coatings.

4.3 Low-Emissivity Coatings

Thin films combining a high transparency in the visible with a high reflectance in the far-IR are of special interest for large-area architectural glazing to reduce heat losses from buildings. Their high costs make TCO materials inappropriate for this purpose. Extremely thin metallic coatings (TCM) made with silver or even gold have in contrast become standard in low-e glazing. To achieve the desired properties, these coatings generally consist of dielectric-Ag-dielectric multilayer stacks, where the thin (~10 nm) Ag layer reflects long wavelength IR back into the building (Figure 6). As for the dielectric layers, they act as anti-reflectance devices and they also protect the silver layer, which would not resist corrosion if exposed to air. Low-e coatings are usually deposited off-line by MS, the dielectric layers are commonly made up of TiO_2 , silicon dioxide, zinc oxide, tin oxide, zinc stannate (ZnSnO_3), bismuth oxide or silicon nitride (Figure 7).

Whereas in the semiconducting TCO materials the charge-carrier density controls the NIR transmittance and reflectance of the film, in the TCM approach, the optical response mainly involves absorption by free carriers in the metal. Modern low-e coatings on glass actually comprise 12 or more layers of metals and dielectric materials in a 300 nm-thick stack. In this multilayer system, the films act as interface, base, seed, conducting, barrier, and cover or protection materials. Because the most advanced products incorporate three silver layers and multiple dielectric layers, they are referred to as a *triple silver* low-e coatings. These layer systems markedly reduce the thermal transfer coefficient U . For a 4 mm-thick single pane of float glass, this coefficient is $5.8 \text{ W/m}^2/\text{K}$ whereas a value of $1.0 \text{ W/m}^2/\text{K}$ is obtained for an insulated double-pane coated system. With triple glass

Figure 7 The actual multilayer structure of low-emissivity glasses: the thin Ag layers sandwiched in between oxide dielectric layers seen in a scanning electron microscopy micrograph of the section of a coated float glass.

solutions, the thermal heat-transfer coefficient becomes very close to that of the walls, namely $0.6\text{--}0.7 \text{ W/m}^2/\text{K}$. Heat losses from buildings can thus be reduced by 55 to 70% with double- and triple-pane low-e coated systems, respectively. The energy savings and improvements in carbon footprint made possible by these systems are thus potentially enormous if one thinks that, in the United States alone, about 20–35% of the \$20 billion winter heating bill is wasted by inefficient windows.

The market for low-e coatings has thus grown considerably as a result of environmental legislation and increasing energy costs. In 2016, architectural applications for coated glass amounted to about 18 million tons (~\$24 billion), which were shared between residential buildings (~10 million tons, \$14 billion) and commercial buildings (~8 million tons, \$10 billion). In the years to come, the compound annual growth rate of both segments would be similar at about 6.4%, leading to an annual architectural coated glass demand of almost 24 million tons in 2021. Beside the world major traditional players in coated architectural glass (AGC, Saint-Gobain, NSG, Guardian, Şişecam, Cardinal, and Fuyao), there are also newcomers in the field, especially in Asia (Chapter 9.6). In recent years, competition on the regional scale is crossing borders and becoming global. To expand the market further, the next generation of low-e coatings is increasingly being deposited onto toughenable glass, which is post-deposition annealed at temperatures up to 650°C . Under these conditions, however, Ag atoms are highly mobile so that they can rapidly diffuse through the other layers in the coating stack, compromising their performance.

4.4 Antireflective Glasses

Silicate glasses have a high transmittance in the visible range. But each of their surfaces reflect approximately 4% of the incoming light, which is too high for various applications; the reflectance R of light at an interface between two media of refractive indices n_1 and n_2 is given by $R = [(n_2 - n_1)/(n_2 + n_1)]^2$ (Chapter 6.1) This is the reason why antireflective structures and coatings are needed for most optical components and optoelectronic devices to reduce undesired optical loss and, thus, improve performance. Reducing reflectance has indeed been an important development task for decades. Various approaches are available.

As noted in the Introduction, the potential to reduce reflectivity by modifying the glass surface was realized early. In 1886, John William Strutt, better known as Lord Rayleigh (1842–1912) discovered that aged glasses with tarnished surfaces have a higher light transmittance than new, clean pieces [19]. The reason was that modified surface layers had been created with a refractive index intermediate between those of the glass and vacuum. Today, antireflective glasses can be generated through structuring of the surface (Chapter 6.7) but most applications use coatings, in particular high-quality AR layers, since their very low reflectivity can be tailored for a given wavelength range.

Practical antireflective coatings rely on interference effects in thin layers (Figure 8). Layers with a thickness of one quarter of the wavelength of light ($\lambda/4 = \lambda_0/(4n_1)$), where λ_0 is the vacuum wavelength, lead to a

minimum reflectance for a normally incident beam. These layers are thus called quarter-wave coatings. A destructive interference is also obtained for thicker coating layers ($3\lambda/4$, $5\lambda/4$, etc.). The simplest interference coating thus consists of a *single quarter-wave layer* whose refractive index is the square root of that of the glass. Two reflections of equal magnitude then arise at the two interfaces, and they cancel each other out by destructive interference. Theoretically, the reflectance is zero at the midpoint wavelength (λ) at normal incidence and reduced for a broad range of wavelengths and angles of incidence on either side of the minimum [10]. The most common optical glasses have an index of refraction near 1.52, so that an optimum single layer coating should have an index of 1.23. But no solid thin-film material exists with such a low value. Magnesium fluoride (MgF_2) coatings were often used in the past because they have a relatively low index of 1.38, which reduces the reflectance to 1%. But the material performs much better on a high-index optical glass with $n = 1.9$. This approach has two limitations, however, because (i) coating materials with suitable refractive index are not always available, particularly when the glass has a relatively low refractive index; (ii) and single-layer coating works only over a limited bandwidth (or wavelength range).

4.5 Multilayer Interference Coatings

As already noted, other important devices are made up of alternating layers of a low-index material, like silica

Figure 8 Light transmission of a series of soda-lime float glass: (a) standard 3 mm-thick sheet; (b) low-iron glass; (c) patterned surface; (d) with one-side antireflective film (for photovoltaic applications). Solar spectrum (top) shown for comparison, the bandgaps of some relevant photovoltaic materials being indicated.

(SiO₂), and a higher-index material, like titania (TiO₂). Reflectivities as low as 0.1% can be obtained at a single wavelength. Coatings that give a very low reflectivity over a broad band can also be produced, although these are complex and relatively expensive. Optical coatings can also be made to comply with special characteristics, such as near-zero reflectance at multiple wavelengths or optimum performance at angles of incidence other than 0°. If antireflective properties are required for a very broad wavelength range (or for different wavelength ranges simultaneously, or for different angles of incidence), more complicated designs have to be used, which are usually developed with the help of numerical simulations. As it happens, there is a general trade-off in such multilayer designs between a low residual reflectivity and a large bandwidth. The so-called *V coatings* have a high performance but only for a narrow bandwidth (10 nm), whereas broadband coatings offer moderate performance over a wide wavelength range [10].

5 Miscellaneous Uses

Different types of interference and AR thin-film systems dominate in the information technology area, which are needed for optical communication and integrated optics components such as narrow band filters, wavelength division multiplexers, wave-guiding films, integrated filters, or reflectors in semiconductor lasers. For contrast enhancement and transparent electrodes, antireflective coatings are needed for display glasses. Many other optical devices require such coatings, for example, camera lenses, eyeglasses including those worn for safety and aesthetic reasons, anti-scratch coatings for ophthalmic glasses, sun-protection and photochromic glasses. Flexible substrates with appropriate films are used for touchscreens, iridescent packaging, lightweight mirrors, bendable displays, and light sources (Chapters 6.9 and 6.10). Thin films are applied for energy saving in regenerative lamps or as cold-light reflectors, colored coatings for traffic/railway signal lights, and for both encapsulating and making transparent electrodes for OLED lighting (Chapter 6.10). Optical components for lasers and other instruments use AR interference coatings, beam dividers, mirrors, filters, variable filters, narrow band spectroscopy filters, fluorescence microscopy filters, etc.

In the energy sector, various film systems are applied on float glass for building insulation, in particular conductive low-e films for architectural windows, solar-energy control films for architectural glazing, coating systems for “smart” windows with variable optical properties, and AR coatings for shop windows. A similar broad spectrum of thin-film systems is used for glass applications in

transport (Chapter 9.2). Coatings are used to heat windows and for heat rejection. Reflective coatings for rear-view mirrors in cars have a long tradition but electrochromic mirrors are increasingly replacing them.

In the household, few products use thin films – for cost reasons. But heat-reflecting coatings are applied to oven windows and as oven wall reflectors. In packaging, the glass surface also dominates. Some containers need simple solutions, for instance, coatings to reduce friction, improve scratch resistance, and increase strength. For pharmaceutical packaging, additional functions are needed including transparent diffusion barriers, UV-absorption, and anti-sticking properties for proteins (Chapter 7.7).

6 Perspectives

Glass has long been used in energy technology. For example, the electrical light bulb could not have been invented without it (Chapter 6.9) whereas early electrical distribution networks used glass as an insulator. Hence, it should not come as a surprise that functional coatings on glass are and will be the enabler for many technological solutions to be found to society’s problems regarding generation, conversion, and saving of energy.

In buildings, cost-effective energy saving can be made with glasses that also satisfy environmental requirements, in particular to replace traditional windows which are a “weak link” in the energy consumption of buildings. For decades, the energy balance has been so much improved in industrial countries with low-e coatings on glass that uncoated glass will not find a market for architecture in the future. To contribute to a reduced carbon footprint, the energy-saving properties of passive coatings should nonetheless be improved with more sophisticated multilayer designs relying on materials such as heavily doped wide bandgap semiconductors, metal films and, in the longer term, carbon nanotubes and meshes. Different solutions will employ optically active coatings with more complex materials and processes. The optical properties (transmittance, reflectance, and absorbance) of chromogenic multilayer systems (i.e. electro-, thermo-, photo-, or gasochromic) will, for instance, be adjusted as a function of the charge, temperature, photon, or gas conditions, respectively. Glass may thus be made *switchable* in different ways at different speeds depending on the technology used. Whereas the response takes minutes in the electro-gel sandwiched in the windows of the Boeing 787 Dreamliner, it is extremely short with polymer-dispersed liquid-crystal molecules (Chapter 6.10) in what are still niche applications. To aim at a wider market new technologies are thus under development, for example, plasmon-

enhanced monochromatic or full-color electrochromic switching through arrays of metallic nanoslits [20].

Functional coatings on glass are already key components of state-of-the-art energy conversion systems such as photovoltaics, concentrated solar power, and solar fuel (Chapters 9–0.4). Whereas high environmental stability and transparency are especially needed for concentrated solar power, thin-film photovoltaics made up of Cu(In,Ga)Se₂ or CdTe/Si on thermally stable glass substrates will be a solution in the future. Various other functions will be relevant in this sector. For increasing light efficiency and transmission, anti-reflecting, patterned, or self-cleaning surfaces are, for instance, needed.

In view of the traditionally high energy consumption of lighting devices, the much more efficient OLED technology based on multilayer coatings on glass is rapidly developing (Chapter 6.9). In addition to highly transparent glass, transmitting conductive coatings with high work functions are needed as an anode. For efficient light extraction, glasses with refractive indices higher than 1.8 are to be preferred. To encapsulate the optically active system, a thin film with an excellent barrier function is the solution of choice, particularly for flexible lightweight lighting systems.

Although they are often not visible in the final product, coated glasses are also the enabling component of many products in information technology. Glasses with suitable coatings, as, for example, transparent electrodes, provide the main interface with the users of display or electrochromic devices. More important, coated flexible glass will be the enabler for many future applications, such as high-performance flexible electronics, displays, touch sensors, photovoltaics, or OLED lighting. For various information-technology products, specific film properties are needed, for example, for mobile information systems, scratch-resistant films (reduction of lateral crack generation), and low-friction films to reduce surface fracture initiation.

For transparent conductive films on glass, which are standard in many information-technology devices today, new or improved materials are needed. To obtain an optimized device performance, very specific thin-film properties are required which are strongly correlated with the specific application. For example, for electrochromic systems, the transparent films must be highly conductive (because a high sheet resistance creates a potential drop that causes inhomogeneous coloration), highly transparent (also in the near IR), chemically inert, and provide rapid injection-ejection and collection of charge. For a photovoltaic top electrode, they should be highly transparent in the absorption region of the absorber, have relatively good conductivity (to avoid ohmic drops), and be chemically durable. For liquid-crystal displays (Chapter 6.10), they need only a moderate conductivity,

but a high transparency in the visible range (no haze) and must be particularly chemically stable. For OLED lighting with a highly transparency glass, they must have a high work function because they act as the anode of the device. This flexibility in film properties is only becoming possible with advances in thin-film deposition technologies.

Glass for Lighting

Hiroki Yamazaki and Shigeru Yamamoto

Nippon Electric Glass, Otsu, Shiga, Japan

1 Introduction

Fire brought light to mankind when it was first mastered about 400 000 years ago and then sustained by any combustible locally available, including animal bones and droppings (e.g. the famous Mongolian *argol*). Only in Antiquity was the torch specially invented for lighting, for instance, in the Roman form of a wooden club on which a mix of sulfur and lime was deposited. Further progress was achieved with *lamps* (from the Greek *lampein*, to shine, which also yielded the Latin *lanterna*) and *candles* (from the Latin *candere*, to shine, and then *candela*, candle) whereby a slowly burning wick generally fed by tallow made much safer and longer lighting possible. Unknowingly to the users, however, what made these flames valuable for lighting were not their maximum temperatures of only 1300–1400 °C, but the soot particles forming as an intermediate step of the combustion process, which emit a rather strong yellow light at these temperatures.

It remained to protect the wick from extinguishment by wind and to prevent the fire from spreading accidentally, which was eventually accomplished in Antiquity with lamps and lanterns. In view of its transparency and non-combustible nature, glass was ideally suited for these appliances. As found in Pompei, transparent glass lamps similar in shape to traditional clay or bronze oil lamps were already made at the beginning of our era [1]. By the fourth century, glass lamps with a metal frame had become common in Italy and the Eastern Mediterranean (Chapter 10.5, [2]). This was especially the case in churches where the natural light coming from large glass

windows was cleverly combined with those of “hundreds of glass lamps set into crown-like structures of precious metal” to guide “the attention of the beholder towards the high altar” [3]. Glass had thus begun a very long career in lighting applications. With new fuels such as whale oil or coal gas, fire lanterns remained well throughout the nineteenth century the only lighting devices in spite of the completely new sources of light that had already been discovered.

Glass had actually played a prominent role in the first of these sources. As observed by Francis Hauksbee (1660–1713) in England and Pierre Polinière (1671–1734) in France, mercury shaken in a Torricelli tube or placed in an evacuated glass vessel connected to a glass electrostatic machine emits a fair amount of visible light (Chapter 10.10), but no attempts were of course made to transpose these *electroluminescence* experiments into practical lighting. Of more immediate interest was thus the discovery of the continuous electric arc made by Vasilii Vladimirovich Petrov (1761–1834) in Saint Petersburg and then by Humphry Davy (1778–1829) in London [4] although the size and cost of the batteries required prevented any extensive applications. It was the invention of the dynamo in 1869 and the availability of relatively inexpensive electric current that eventually opened the way to artificial lighting. Whereas glass was valuable for fire lanterns, it became indispensable for electric lighting because it was the only material available to protect tightly the light source against atmospheric agents without chemically reacting with it, to withstand the heat produced, to absorb as little light as possible, and to obtain readily the shape appropriate for the intended use of the lamp.

Electric arc lamps were ideally suited for public lighting, thanks to their extremely high luminosity, which was originating in the 3600 °C temperature of the arc and strong luminescence of the ionized carbon vapor produced [5]. The first permanent display was made during

the 1878 *Exposition Universelle* when the electric arc *candles* of the Russian electrochemist Pavel Yablochkov (1847–1894) were installed along the Avenue de l'Opéra in Paris with their glass protecting covers (Figure 1). Although ingenious devices were designed to move continuously and replace the rapidly consumed carbon electrodes, electric arc lamps suffered from UV emission and fire hazards, so their uses became restricted to applications such as search lights (until World War II) for which their extremely high luminosity could not be matched by other means. For other applications, they could not compete with the incandescent lamps and their carbon filaments shining in a glass bulb that were pioneered from the 1830 before being mass produced half a century later, thanks to Thomas Edison (1847–1931) and other inventors, with bulbs first evacuated and from 1913 filled with an inert gas to improve both filament lifetime and luminous efficacy.

As testifies the name *candle* given by Yablochkov to his invention, however, both electric arc and incandescent lighting were still working on the same principle as the

antique oil lamp in that the fuel had simply been replaced by electricity and the wick by carbon electrodes and filaments, respectively. A radical change in lighting applications thus took place when the work done during the last decades of the nineteenth century on electrical discharges in evacuated glass tubes (Chapter 10.10) resulted in the invention of mercury and neon glow lamps more than two centuries after Hauksbee's and Polinière's observations: light was no longer emitted from a small very hot spot but from the whole large volume of a cold device. A better understanding of the atomistic mechanisms of light generation and conversion subsequently led to a number of other innovations. Fluorescent lamps, which convert ultraviolet rays to white light with phosphors (Chapter 7.9), were launched on the market by General Electric in the United States in 1937. Various appliances followed suit, such as tungsten-halogen, sodium, metal-halide, and xenon lamps, and recently solid-state lighting with inorganic and organic diodes. Thanks to better color rendering, improved energy efficiency, and longer lifetimes, they are now widely used for indoor and outdoor lighting, interior lighting for automobiles and other vehicles, and various display devices (Chapter 6.10).

As will be described in this chapter, glass has been involved all these advances because original compositions or forming technologies had to be designed to satisfy the demands of the new light sources (Table 1). A well-known example is the lead borosilicate Nonex (non-expansion) glass invented in 1913 by Corning to solve the very serious problem caused by the breakage of the arc lamps of trains caused by thermal shock under rainy conditions (Chapter 7.6). Whereas transparency (or instead coloration), gas tightness, electrical insulation, mechanical resistance, chemical durability, and versatile formability have kept their fundamental importance, attention has also been paid to thermal resistance and weldability, in particular with metals, which are putting strong constraints both on thermal expansion and on wavelength-conversion properties. In addition, growing environmental concerns have led to the development of new glass compositions free from hazardous elements such as lead and cadmium.

2 Glass for Incandescent and Electric Discharge Lamps

2.1 Incandescent Lamps

Incandescent lighting relies on blackbody emission whose intensity grows as the fourth power of temperature and maximum intensity shifts to shorter wavelengths according to Stefan–Boltzmann law. Operation temperatures must thus be as high as possible to increase both the

intensity of the radiation and the proportion of visible light. Tungsten has long replaced carbon for filaments because it is the pure metal having the highest melting temperature (3400 °C) and lowest vapor pressure along with good mechanical properties at the actual working temperature of about 2500 °C. But the brittle tungsten must be coil-shaped to maximize the surface area of the filament, which is a kind of an engineering feat [6]. Bulbs were initially handblown. Even at rates that could reach 100 pieces per hour and per worker in England in the early 1910s, production was too slow to allow electric lighting to spread rapidly.

Hence, it was mechanization that allowed the United States alone to produce 200 million bulbs in 1919 [7] at a time when glass bulbs represented more than 50% of the sales of Corning [8]. The first machines duplicated the blower's operations: gob gathering by suction, dropping of gob onto blow pipe, blowing and then sagging of parison, and final bulb blowing. In 1923, 11 of the new machines produced over 100 million bulbs in the United States. From 1921 a glass blower named William Woods began to design at Corning a completely different machine, which would remain in use throughout the twentieth century. In 1926 a yield of 300 bulbs per minute was obtained from a continuous glass ribbon originally moving at 0.6 m/s on a series of metal plates, "with one operator, four mechanics, one relief operator, and one transfer mechanic" [8]: holes in the plates allow the glass to sag and be blown (with blow heads and molds moving onto two caterpillar belts at the same rate on both sides of the ribbon) to be eventually cracked off from the rest of ribbon at the cold end of the production line [7].

For the bulb protecting the filament, the glass must have a high electrical resistivity, have a good chemical durability, and be readily sealed with metals and other glasses to ensure excellent tightness with respect to the atmosphere and no or a minimal release of the filling gases. The glass must be highly transparent in the visible range and also, in some cases, in the infrared or ultraviolet, without becoming colored by solarization and UV irradiation. Because resistance to thermal shock is made easier by the thinness of the bulb, a standard soda-lime glass is used, which may be colored if needed (Chapter 6.2). If not, its inner surface is generally coated with colloidal silica microparticles by electrostatic coating to disperse the light evenly. The bulb size increases with the amount of heat to be dissipated, whereas its shape and color depend on whether the lamp is used for interior, automotive, or special lighting, decorative illumination, or electronic equipment. The bulb is tightly sealed with the metal base to be first evacuated and then filled with inert gases to prevent tungsten from oxidizing and evaporating. Along with some nitrogen as an anti-arcing agent, the filling gas is generally argon, occasionally krypton, or even xenon (for lowering tungsten

evaporation by larger atomic size and mass), at a pressure of 80% of the atmospheric value to avoid overpressurization upon use.

Glass is also used for the inner stem that supports the filament, insulates the electric lead-in electric wires and the associated fuse that prevents arcing upon filament breakage, and encloses the exhaust tube serving to evacuate the bulb before filling it with gas (Figure 2). For the stem, lead glasses have been the traditional choice because of their high electrical resistance and formability. For environmental reasons, however, they are now replaced with newly developed lead-free barium- and strontium-bearing compositions. In this case, the mixed-alkali effect on electrical resistance (Chapter 4.2) has served to keep the insulation without affecting the sealing workability and good chemical resistance of the material [9]. Initially lead-in wires also raised a problem because the thermal expansion coefficient of copper of $18 \times 10^{-6} \text{ K}^{-1}$ is two to three times higher than that of the glass. The solution was found in 1911 by means of the so-called Dumet (dual-metal) wire seal, namely, a Ni42–Fe58% core thinly sheathed with brass, enclosed in a copper shell, brazed, drawn to the intended diameter, and finally coated with sodium tetraborate for better wetting with the glass. With a typical 18–28 wt % Cu fraction, the thermal expansion coefficient of the

Figure 2 Sketch of an incandescent lamp.

Figure 3 Automotive lamps with either a metal (left) or a wedge (right) base.

wire is about 6.5 and $9.0 \times 10^{-6} \text{ K}^{-1}$ longitudinally and radially, respectively.

For high power or outdoor lamps, the resistance of the bulbs to thermal shock has been achieved with borosilicate glasses whose thermal expansion coefficient is especially low (Chapter 7.6). The sealing metals are then tungsten or molybdenum, whereas the stems are also made up of borosilicate glass. The picture is more complex for automobile (and other transportation) applications because the same lamps are not used for stop lights, direction indicators, room lights, and various types of display illumination. Two types of lamps with different bases are distinguished (Figure 3). With a metal base, the aforementioned soda-lime and lead-free glasses are used for bulbs and stems, respectively. For wedge-base bulbs, a lead-free glass can directly seal the electrodes into glass bulbs, thanks to its good sealing workability and high electric resistance. For direction indicators, a colored glass produces the orange light stipulated by laws and regulations. This orange hue was obtained by addition of CdS-CdSe to the bulb glass. For environmental reasons, however, bulbs for direction indicator lamps are now made with lead-free glass colored with MoS [10].

2.2 Tungsten-Halogen Lamps

The major disadvantage of incandescent lamps is their lighting inefficiency as more than 95% of the energy spent serves to heat the bulb and to emit directly IR radiation, which is why they have been progressively banned in many countries. With tungsten-halogen lamps this efficiency is improved through mixing of bromine or iodine gas with the inert argon or krypton gas filling the bulb (Figure 4). These are the well-known *halogen lamps* featured in households, stores, and especially the headlights of automobiles with their higher luminosity and longer lifetime. They rely on the tungsten-halogen cycle whereby the halogen gas reacts with the tungsten evaporating from

Figure 4 Sketch of a tungsten-halogen lamp.

the filament to form a tungsten halide, which, when brought by convection next to the filament, decomposes on it back into tungsten and halogen gas. Even though tungsten does not deposit only in places where it would be needed, filament damage is limited, and blackening of the glass bulb caused by tungsten deposition is strongly reduced. In turn, these features make it possible to increase the temperature and luminance of the filament and, thus, its efficiency by 30% with respect to its plain incandescent counterparts, for the same lifetime.

To keep the tungsten-halogen cycle going, however, the condition to be respected is that the temperature of the inner wall of the glass bulb remains higher than 250°C , which is the reason for the small size and tubular shape of the bulb. Because temperatures higher than 500°C can obtain in high-power lamps, the tubes are made from high-strain-point glasses able to withstand temperatures of up to $\sim 800^\circ\text{C}$. At such high operating temperatures, water or other gases could diffuse out of the glass and inhibit the halogen cycle. Glasses with water contents lower than 10 ppm are thus required to prevent bulb blackening and to avoid premature failure of the filament. In addition, lamps can be coated with infrared reflective dichroic films such as $\text{TiO}_2\text{-SiO}_2$ or $\text{Ta}_2\text{O}_5\text{-SiO}_2$ to improve the light-emitting efficiency by reflecting back the infrared radiation emitted from filaments whose energy consumption is then reduced.

In general, quartz glass is used for these tubes because of its very high strain and softening points, excellent thermal resistance, and high thermal shock resistance, thanks to its low thermal expansion coefficient. But no metal matches this low expansivity. As a solution, molybdenum foils are used to reduce the stress caused by the expansion mismatch. Quartz glass also transmits ultraviolet rays that would, for instance, result in resin degradation, which is why it is doped with TiO_2 , CeO_2 , etc. or coated with UV-absorbing films. For small halogen lamps, an aluminosilicate glass is used instead along with

molybdenum lead-in wires that match the glass expansivity. In this case, harmful ultraviolet rays are not an issue because they are absorbed by the glass.

2.3 Fluorescent Lamps

Light is emitted in a completely different and more energy-efficient way in discharge fluorescent lamps. Thermal electrons are emitted from tungsten filaments placed at the opposite ends of a tube filled with a low-pressure mercury vapor and an inert gas such as argon, whose ionization increases electrical conduction of the internal space. To enhance the release rate of electrons, the filament is not only coil-shaped but coated with alkaline earth oxide emitters [CaO, BaO, SrO]. When accelerated by an a.c. voltage at high enough energies, the emitted electrons collide along their way with Hg atoms in which they induce a 4.9 eV transition to a higher electronic energy level. Deexcitation then causes the emission of a UV radiation at a wavelength of 253.7 nm. The UV rays are finally transformed into visible light upon impact on phosphors deposited on the inner surface of the glass tube (Figure 5), with which an excellent color rendering may be achieved.

The tubes are shaped with the Danner or Vello processes described in Chapter 7.7. Initially soda-lime glasses were used for straight tubes, and lead glasses for circular, compact, and bulb-shaped tubes requiring good workability during thermal processing for forming bent and complex shapes (Figure 5). As matter of fact, it was

Figure 5 Various types of fluorescent lamps: straight tube, circular line, compact type, and bulb shape.

glass-forming difficulties that prevented compact designs with the same base as for incandescent lamps from being produced earlier than in the late 1990s. Lead glass was also used for the stems of all types requiring good sealing workability and a high electric resistance. A soda-lime-silicate glass containing an appropriate amount of B_2O_3 with excellent workability for forming and sealing has now been developed to reduce these environmental burdens [11] and is used for all types of lamps. A small addition of antimony oxide to the glass composition prevents UV darkening of the bulb.

Cold-cathode fluorescent lamps have been extensively used for the backlight of liquid-crystal displays (Chapter 6.10) until white LEDs were developed. These lamps have a smaller diameter, a greater length, and a higher luminosity, so glass tubes must have a higher thermal resistance and strength during processing. Borosilicate glasses fit well these constraints, but 0.1–5.0 wt % TiO_2 has to be added to the composition [12] to absorb the UV radiation emitted to prevent the transparency of tubes, the light-guiding plate, and reflectors from degrading. As to the lead-in wires, they are made from a Fe–Ni–Co alloy, molybdenum, or tungsten in conjunction with a glass of a matching thermal expansion coefficient.

In the so-called black lights, advantage is in contrast taken of the UV radiation emitted. Along with little or no visible radiations, the long-wave ultraviolet (UVA) produced by these lamps is used in a variety of applications ranging from mineral identification, medical diagnostics, or bacterial disinfection to special lighting effects or the detection of counterfeit banknotes. Glasses colored by nickel and cobalt oxides are used for absorbing the visible light and transmitting only the near ultraviolet at wavelengths of 300–400 nm. For germicidal lamps, a glass with low impurities, especially very low iron oxide content, is alternatively used to transmit UV light at its emission wavelength of 253.7 nm.

2.4 High-Intensity Discharge Lamps

When visible light is produced by the collision of discharged thermal electrons with gaseous metal emitters, another way to increase the efficiency, luminosity, and lifetime consists in increasing the vapor pressure and the temperature within the lamp [13]. Mercury, metal-halide, and high-pressure sodium lamps are such HID devices. They are used for the headlights of automobiles and as light sources for projectors, including interior and exterior wide-area lighting.

These lamps have a complex structure consisting of an outer jacket and a tube within which an electric arc is established between doped tungsten electrodes. After a warm-up period, a light characteristic of the sealed gases

Figure 6 Sketch of a high-pressure mercury lamp.

is emitted (Figure 6). The arc tube is generally made of quartz glass to ensure good thermal resistance and insulation along with a high resistance to devitrification at the high temperatures and pressures of a few tens of bars of operation. It also requires a low content of water, which, if released, would shorten the lamp lifetime and cause failure when discharge is initiated [14]. The jacket maintains the temperature of the arc tube to raise the vapor pressure of the metal and, when filled with nitrogen, to prevent the metal components from being oxidized. Low-expansion borosilicate glass with a high thermal and thermal shock resistance is thus used because temperatures of several hundred degrees can obtain during lighting.

As in fluorescent tubes, argon is also introduced in high-pressure mercury lamps to make discharge easier. Molybdenum foils are used as sealing metals. Upon prolonged operation, strong UV emission would cause contraction and accumulation of tensile stress on the inner surfaces of the outer tubes because of the contraction of glasses containing of B_2O_3 or GeO_2 induced by UV rays [15]. In addition, quartz glass also contracts when exposed to UV rays with a shorter wavelengths and higher energies such as 9 eV [16]. Because mercury lamps generate a light with a bluish white hue, this feature may be eliminated if phosphors emitting red light are deposited on the inner surface of the outer jacket.

In metal-halide lamps the main light emitters are sodium, thallium, and indium bromides and iodides, to which mercury, argon, and various elements are added to enhance electric discharges and improve color rendering. Metal halides evaporate more easily and emit a stronger light than the elemental metal, whereas the lifetime of lamps is prolonged, thanks to the inhibition of the reaction with arc tubes. As an alternative to the usual quartz tubes, alumina ceramic arc tubes have recently

been developed [17] along with Al_2O_3 - Dy_2O_3 - SiO_2 glass-type sealants.

High-pressure sodium lamps are filled with sodium as a luminescent element in addition to mercury and xenon or argon. They emit a specific orange light. A translucent alumina ceramics not reacting with sodium vapor at high temperatures is then selected for the arc tubes. Niobium metals are used as a sealing metal with Al_2O_3 - CaO -type glass frits because they match their thermal expansion coefficient and are highly durable with respect to sodium vapor [18].

2.5 Xenon Lamps

Xenon is another common light source if brought to a pressure of 25–30 bars in electric arc discharges between tungsten electrodes. Quartz glass is again used for the arc tubes, which must be water cooled to dissipate the heat produced by the impact of electrons on the anode. These lamps have an excellent color rendering because their spectral distribution is close to that of natural light. Thanks to their high luminance and long lifetime, they are used for projectors, printing plate making, solar simulators, or analytical instrumentation such as atomic absorption spectrometers (Chapter 5.1). A pulsed light emission is also possible with xenon lamps. Owing to the low amount of heat produced, these can then be miniaturized to serve as flash lamps for cameras. Because the temperature of the light-emitting parts is relatively modest, a low-expansion borosilicate glass can sometimes be used. In this case, tungsten is used as a sealing metal.

3 Glass for Solid-State Lighting

3.1 General Considerations

Solid-state lighting with light-emitting diodes (LEDs) and organic LEDs (OLEDs) is becoming common and even predominant in electronic devices, thanks to an excellent energy efficiency higher than 100 lumens/W combined with a high luminance and a long lifetime. In these latest technologies light is directly emitted by diodes when application of an appropriate current causes excess electrons of an n-type semiconductor (N) to flow and recombine with electron holes of a p-type semiconductor (P). The energy difference between the conduction and valence bands of the N and P regions, respectively, is released not only as heat in Si or Ge but also as light in other semiconductors such as gallium arsenide phosphide [GaAsP] or gallium phosphide [GaP].

After the discovery of this phenomenon of electroluminescence in 1907 on silicon carbide [SiC], much work has been carried out to improve its efficiency and to extend

the range of emission wavelengths, not only directly but also through phosphor fluorescence. A major achievement in this respect has been the invention in 1994 of an InGaN-based semiconductor diode emitting a bright blue light. It became possible to produce radiations of shorter wavelengths for the whole visible part of the spectrum with appropriate phosphors (Chapter 7.9). Further progress has lead lighting with LED to develop steadily since the early 2000s, a growth that is now enhanced by OLEDs. Although solid-state lighting does not need vacuum- or gas-tight containers, it does involve glass. For LEDs, glass is used either as matrix for dispersing and protecting the phosphors that convert the wavelength of the light emitted or as shield for the newly developed quantum dot wavelength converters embedded in resins. For OLEDs, glass is used as both a substrate for the very thin, uniform organic layer and a sealant protecting the organic material from reaction and subsequent degradation with oxygen and water [19].

3.2 Light-Emitting Diodes

In a typical white LED (Figure 7), phosphors convert a part of the blue light emitted, for instance, into yellow with Ce-doped yttrium aluminum garnet (YAG) or into red or green with sulfide or nitride phosphors. The white light then results from combination of these new wavelengths with that of the nonconverted blue light. A mix of these *wavelength-conversion* materials can thus be used to optimize the color rendering properties of the light produced. Another useful implementation is, for example, a combination of a violet LED with red, green, and blue phosphors.

Silicones are common matrices for dispersing these phosphors in LEDs, but they suffer from three main disadvantages. The first is the inhomogeneous distribution of phosphors that results from density difference between

Figure 7 Sketch of a commercial white LED.

the resin and phosphors and prevents the desired chromaticity and luminance from being achieved. The second is the permeability of resins to water, which makes degradation of some types of phosphors possible. And the third is a sensitivity of resins to the heat and strong light generated by LEDs in high-luminance applications, which may result in discoloration and reduced light intensity.

Glass matrices are free from these problems if they are appropriately chosen to avoid reactions with phosphors. New wavelength-conversion materials are thus manufactured from a mixture of glass powder sintered with fluorescent substances. Borosilicate glasses of the type $\text{SiO}_2\text{--B}_2\text{O}_3\text{--RO}$ [$\text{R} = \text{Mg, Ca, Zn, Sr, Ba}$] can, for instance, be used to sinter Ce-doped YAG. At lower temperatures $\text{SiO}_2\text{--B}_2\text{O}_3\text{--ZnO}$ and $\text{SnO--P}_2\text{O}_5\text{--B}_2\text{O}_3$ glasses can be alternatively selected for sulfide or nitride phosphors. A more uniform dispersion phosphors is achieved with these glasses, which makes it possible to control precisely the chromaticity and luminance through adjustment in the material thickness in the desired shape (e.g. plate, bar, dome, etc.). In addition, a higher luminous efficiency results from the dispersion of the excitation light by the phase boundaries, bubbles, and microcrystals generated by the sintering process, whereas the glass gas tightness prevents oxygen and water from penetrating the material and degrading the phosphors. Finally, such glass-based materials are highly resistant against discoloration and deterioration even when used for high-luminance applications [20, 21].

3.3 Quantum Dot Light-Emitting Diodes Backlight

In ongoing advances, attention is being paid to *quantum dots*, namely, tiny semiconductor particles whose nanometer size give them special electronic and optical properties, which are intermediate between those of isolated atoms or molecules and of bulk semiconductors. By adjusting the size of the quantum dots (Chapter 6.8), one can in particular tune their fluorescence wavelength and, thus, obtain more vivid images through a finer reproduction of the range of colors as done in the backlight of a liquid-crystal display panel (Chapter 6.10).

A disadvantage of quantum dot fluorescent substances is low resistance to water, however, which makes these phosphors liable to fast deterioration when dispersed in a resin matrix. A new sealing technology with glass thus is under development to avoid the problem (Figure 8). The package contains a quantum dot–resin matrix, which is itself protected against water by a glass seal. The package must be laser sealed to avoid the heat damage on

Figure 8 A quantum dot packaging under development.

either the quantum dots or the embedding resin that would result from ordinary sealing processes at several hundred degrees Centigrade. Upon laser sealing, in contrast, the glass is specifically heated by absorption at the wavelength of the laser beam, so its interior remains unheated [22, 23].

3.4 Organic Light-Emitting Diodes

With respect to LEDs, OLEDs feature still lower power consumption and better color rendering with the light emitted by electroluminescent organic substances such as polyfluorenes $[(C_{13}H_8)_n]$ or poly[*p*-phenylene vinylene], PPV $[(C_8H_6)_n]$. In contrast to LEDs, they are not bright point sources but extended surface lights [24]. They are currently incorporated in flat display panels (Chapter 6.10), but previous work has also made use of them as transparent lighting panels, for instance, inserted in windows.

Because of its relatively high electrical resistivity, the electroluminescent substance is inserted in the form of a thin film sandwiched between two thin-film electrodes, at least one of them being transparent (the anode, made up of indium-tin oxide [ITO]). When an electric field is applied between these electrodes, electron holes are injected by the anode into the emissive layer where they recombine as excitons with electrons coming from the cathode, which then release light and heat when relaxing to the ground state of the valence band (Figure 9). In practice, two additional films are inserted between the electrodes and the emissive layer to optimize hole and electron transport, whereas some transition metals are added to the emissive layer to improve light production by excitation relaxation. As to the whole assembly, it must rest on a substrate that must perfectly smooth and have a constant thickness, which can be made of metal, resin, or glass.

The emissive layer is highly sensitive to water and oxygen, which makes in principle glass preferable to resins for transparent, gas-tight substrates. In contrast to glass, however, resins are flexible, which makes the design of

Figure 9 A simplified sketch of the light-emitting mechanism of an OLED.

Figure 10 Effects of the indices of refraction of the glass substrate and ITO electrode on the light exiting from and remained trapped in an OLED.

bendable OLEDs possible and in addition allows for continuous production process from rolls instead of plates to improve productivity. For improved bendable OLED lighting, a non-alkaline aluminoborosilicate glass substrate has thus been developed and is produced by the overflow downdraw method (Chapter 1.4) with a 50–100 μm thickness for which a roll-to-roll process is under development [25].

Currently the most important issue is to increase the emitting efficiency of OLEDs by reduction of the mismatch between the refractive indices of their structural components. With an index of about 1.5 for the glass substrate and values ranging from 1.9 to 2.1 for the emissive layer and ITO electrodes, the incident light at angles greater than critical angle cannot transmit the substrate, so the lighting efficiency is limited to about 20% (Figure 10). One can thus make a glass substrate with a higher refractive index by incorporating SrO , BaO , ZrO_2 , TiO_2 , La_2O_3 , or ZnO into the composition. Alternatively, one can achieve a high refractive index by grazing powdered glass so as to increase the critical angle at the substrate–electrode interface [26] and, thus, to increase the amount of light transmitted. As a matter of fact (Figure 10), the latter design can be combined with

Figure 11 Inclusion of a highly refractive glass and a light-diffusive structure for improving the amount of light actually produced by an OLED.

the addition of a scattering layer to raise further the efficiency of light extraction from the substrate to the air [27–29]. Of course, the aforementioned laser technology can also be used for sealing the substrate without needing a drying agent [30].

4 Perspectives

To summarize the advances made in lighting devices throughout the ages, it will suffice to mention that candles typically have a luminous efficacy of about 0.2 lm/W, incandescent bulbs of 8–15 lm/W, fluorescent tubes of 70–100 lm/W, high-pressure sodium lamps of 90–150 lm/W, and LEDs of 100–170 lm/W, whereas the luminous efficiency (i.e. the fraction of energy not lost as heat) has in parallel increased from 0.05 to 30%. In this history, a striking feature has been that major improvements in century-old lamps have been made shortly before they became obsolete. The 5–10 times more luminous version of the oil lamp with a hollow circular wick, a glass chimney, and air control was, for instance, invented in 1780 by Ami Argand (1750–1803) in Geneva. Likewise, mechanization of candle production was achieved only at the beginning of the nineteenth century when electric lighting was about to be invented. Since then improvements have been much more rapidly as exemplified by the coiled tungsten filament used in incandescent bulb from the late 1910s, which has then be used in fluorescent and other lamps. Particularly in the last three decades, the rate of innovation has considerably accelerated, thanks to the advances made in both basic physics and materials engineering. The miniaturization of light sources down to the pixel size that has been at the roots of the recent display revolution is especially noteworthy (Chapter 6.10).

Along this evolution glass engineers have always found the solutions to the original problems raised either by these new light sources or by their improvements with respect to energy efficiency or color rendering through the obtained wavelength distribution. In these advances, composition has been as usual the main factor acted upon

to achieve the desired properties, but other important progress had also to be made in terms of processes, for example, to produce the stable ultrathin glass sheet used in flexible devices. Since all efficient luminescent phenomena currently known have been put to use in lighting devices, it is not easy to guess what kind of new light sources could be invented. But glass scientists and engineer can nonetheless feel confident that they will be able to solve the new problems that would be raised by new lamps in terms of both properties and processes. Such a new problem is in fact currently raised by quantum dots, which are less heat resistant than conventional phosphors, so new glasses have to be developed with low softening point and sintering temperatures to achieve a high luminous efficiency and a long life expectancy.

Screens and Displays

Kei Maeda

AGC Inc., Research Center, Hazawa-cho, Kanagawaku, Yokohama, Japan

1 Introduction

From computer screens to cell phones and from TV sets to advertisement panels, the ubiquity of information displays is one of the most visible manifestations of the late twentieth-century electronic revolution. What might be less obvious, however, is that glass is a critical component of all these devices (Figure 1). Ever since the beginnings of artificial lighting, glass has in fact been such a component because it is the only material available to protect the light source against atmospheric agents without chemically reacting with it, to absorb as little light as possible, and to obtain readily the shape appropriate for the intended use (Chapter 6.9). These advantages are of course still put to use in modern displays, but additional and much tighter material constraints have now to be satisfied because of the complex ways in which large, high-resolution images are generated in flat-panel displays (FPD).

Of particular importance are the heat treatments performed at temperatures as high as 600 °C during the fabrication process to deposit on glass surfaces the various elements required for color light emission. Such features have made it necessary to develop new, alkali-free glass compositions with higher strain points such that, through greater thermal stability, irreversible high-temperature deformation is avoided. Likewise, chemical durability has been improved to allow for more aggressive etching of glass surfaces and, thus, to speed up the fabrication process and ensure better adhesion of the deposited

devices. Finally, efforts have also been made to lower density and, thus, to reduce both gravitational sag and the weight of the appliances and also to match better the coefficient of thermal expansion of the glass with that of the silicon of the electronic chips.

Because it has dominated the display industry for more than half a century with billions of TV sets produced, cathode-ray tubes (CRT) will be described first. One of their main limitations is their large volume since they must be deep enough to allow electrons to be accelerated at speeds such that luminescent ions deposited on a glass screen are excited upon impact to produce images. Turning to FPDs, the manner in which material constraints have been satisfied will then be dealt with in the rest of this chapter. To produce them, the first solution was to rely on a backlight to excite much more sensitive substances than phosphors, namely, liquid crystals. Following liquid-crystal displays (LCD) in the early 1990s, further advances have been made with plasma-display panels (PDP) and then organic light-emitting diode (OLED) panels whose higher luminosity and brightness is ensured by light production on the screen itself.

After their appearance in the early 1990s, FPDs have dominated the market as early as in the mid-2000s, thanks to their large size combined with low volume, operating voltage, energy consumption, environmental and breakage hazards, and even fabrication costs. For all of these displays, the race toward larger panels has also required improvements in the production process to reduce considerably the density of glass defects. This topic is beyond the scope of this chapter, however, because the two main processes used for making FPD glass, namely, float and drawdown, are described in Chapter 1.4. It will suffice here to summarize the very rapid advances made in this respect by the increase

Reviewers: S. Inoue, National Institute for Materials Science, Ibaraki, Japan

T. Yano, Chemistry and Materials Science, Tokyo Institute of Technology, Oookayama, Meguro-ku, Tokyo, Japan

during the last two decades of the biggest LCD panels commercialized (Figure 2), a trend that has been paralleled by a large and continuous decrease of production costs. Likewise, the way in which visible light is emitted by phosphors deposited on screens in CRTs and PDPs will not be dealt with because the luminescence process involved is described in Chapter 6.3. We will simply note that a great many different inorganic luminescent materials may be deposited on the glass screen (e.g. $\text{Y}_2\text{O}_3\text{:Eu}$, $\text{Zn}_2\text{SiO}_4\text{:Mn}$) with a grain size a few microns.

Figure 1 The many different functions of glass in a cellular phone. The example of liquid-crystal display: cover for protection of the device against scratches and shocks, touch sensor for detection of the user's commands, front glass for the color filter creating the image, back glass for supporting all thin-film transistors (one per pixel), and guide plate for transmission of the light produced at the edge of the device to the liquid crystals.

Acronyms

CRT	cathode-ray tube
CTE	coefficient of thermal expansion
FDP	flat-panel display
ITO	indium-tin oxide
LCD	liquid-crystal display
OLED	organic light-emitting diodes
PC	personal computer
PDP	plasma-display panel
TFT	thin-film transistor

2 Cathode-Ray Tubes

Television has been a by-product of the physics revolution of the late nineteenth century when the study of electrical conductivity in rarefied gases enclosed in glass vessels led to the discovery of the so-called radiant matter. When an absorbing obstacle was inserted along its pathway, a striking feature was that one would observe its shadow image at the other end of the tube (Figure 3). Radiant matter then became termed cathode rays, whose impact on the other side of the glass vessel resulted in the emission of X-rays as first observed by Wilhelm Röntgen (1845–1923) in 1895 in Würzburg (Chapter 10.10). Shortly after, cathode rays turned up to be electrons

Figure 2 Size increase with time of mother glass in TFT-LCD.

Figure 3 An early image produced by William Crookes (1832–1919) with a cathode-ray tube: electrons emitted by the heated cathode and accelerated toward the cross-shaped anode whose shadow is seen at the other end of the tube [1].

accelerated between the cathode and anode, the first sub-atomic particles discovered by Joseph John Thomson (1856–1940) in 1897 in Cambridge.

Going from the primitive static image of Figure 3 to dynamic ones might seem to have been a real challenge. As soon as 1897, however, the German physicist of radio-wave fame Karl Ferdinand Braun (1850–1918) took advantage of the known deflection of cathode rays by magnetic fields to visualize current and voltage waveforms in two dimensions on a mica plate coated with a phosphorus paint; the trick was to deflect a narrowly collimated beam with the modulated field created by a coil whose axis was perpendicular to that of the glass tube.

The use of the back panel as a screen then made the oscilloscope the very first imaging instrument (actually with electrostatic deflection by two pairs of vertical and horizontal plates). To design a television – a term coined in 1900 in French by the Russian scientist Constantin Perskyi (1854–1906), the following step was to transform an image into an electric current and to form it back on a screen. In 1907, Boris Rosing (1869–1933), for instance, used in St. Petersburg an alkali metal photocell for his *electric telescope*. Through intense international competition, further progress in image scanning and signal amplification allowed the first radio-transmitted images to be broadcasted with a resolution of a few tens of lines by John Logie Baird (1888–1946) in London or Kenjiro Takayanagi (1899–1990) in Japan in 1926. Although the first commercial broadcast of television took place in England in 1937, it was only after World War II that TV sets became household fixtures with an improved resolution of more than 500 lines. Color pictures were then

Figure 4 Sketch of a television cathode-ray tube.

produced in the 1960s with three distinct electron guns for red, green, and blue, whereas the resolution later increased up to 1000 lines.

Three different parts constitute a CRT (Figure 4), namely, the neck, shaped by drawing, where the electron guns are located; the panel, shaped by pressing, where the image is formed; and the funnel connecting them, also formed by pressing. Obvious material prerequisites are that the evacuated glass tubes sustain the atmospheric pressure exerted and strongly absorb the X-rays emitted to prevent them from being transmitted to the viewers. In addition, the glass must have a specific light transmittance that does not degrade upon irradiation by electrons and X-rays as well as a high enough volume electrical

Table 1 Chemical composition (wt %) of glasses for color cathode-ray tubes.

	Panel	Funnel	Neck	Seal
SiO ₂	60.5	50	50	3.4

resistivity to maintain electrical insulation in spite of the high accelerating voltages applied.

All these constraints are satisfied by glasses bearing high contents of heavy metals (Table 1, [2]). The X-ray absorbance must in fact be higher for color than for monochrome TV because a higher accelerating voltage (30 vs. 20 kV) is required as an important fraction of the electrons emitted is absorbed by shadow masks that remove those that would otherwise impact the wrong phosphors. Lead is by far the most efficient absorbing element (Table 2), but it has been restricted to the neck, the thinnest part, because of yellow color centers produced upon irradiation and of environmental concerns about recycling after use (Chapter 9.8). The less problematic barium and strontium are thus used for the thicker funnel and panel.

The funnel and the neck glasses can be mutually welded because their compositions and softening temperatures of about 650 °C are very close. With a higher softening point of about 700 °C, the panel glass must in contrast be sealed with a low-melting glass frit whose typical composition is included in Table 1 [3]. Finally, special attention must also be paid to the thermal expansion coefficients (CTEs) of both parts to minimize thermal stress and, thus, failure problems.

Table 2 Effect of cation atomic weight on the mass absorption coefficients of the main metal oxides at a wavelength of 0.06 nm [2].

Oxide	Mass absorption coefficient

3 Glasses for Flat-Panel Displays

3.1 General Considerations

Schematically, the function of glass in a CRT is to be an evacuated vessel in which electrons freely propagate until they hit at one of its ends a screen on which phosphors have been deposited to produce images. Except for forming processes and compositional adjustments required for X-ray absorption, these two functions did not require special technological advances. The situation has been quite different with FPDs for which really new glasses and processes had to be designed.

First, devices such as cell phones and tablet computers require cover glasses to be resistant to wear and consistent with the so-called touch-display technologies. Second, the strong customer demand for thin and lightweight devices requires to use thinner glass panels without compromising their physical properties. Third, the image information is no longer transmitted as modulated electrical currents (deflecting electron beams) but as digital bits that must be transformed back into visible electromagnetic radiations on the screen itself: to command individually each pixel, X–Y arrays of tiny electrodes are needed, which must in addition be transparent. Fourth, upon use the glass must not react in any way with the other components of

Figure 5 Thermal compaction of a glass upon structural relaxation in the glass transition range.

the screen. And fifth, as already noted, the various devices used to produce light pixels are implanted through high-temperature treatments after which the relative positions of two given points on the panel should be constant to within about $1\ \mu\text{m}$.

3.2 The Problem of Thermal Compaction

In high-temperature treatments of glass, the major problem encountered results from volume relaxation if the glass transition range is approached (Figure 5; see also Chapter 3.5). Known as thermal compaction, this effect is due to the fact that the volume of the glass then tends to relax to its equilibrium value. Because the fictive temperature of the glass is necessarily higher than the treatment temperature, the result is a volume decrease at a rate and by an amount that both depend on the difference between these two temperatures and also on glass composition. The most efficient way to limit the effect is of course to increase the glass transition temperature through compositional modifications.

The problem is especially important in the fabrication of PDPs, whose process requires maximum temperatures of around $600\ ^\circ\text{C}$ that exceeds the strain point of the substrate glass. A comparison of these effects is made for a soda-lime glass and a high-strain-point glass specially designed for PDPs [4] whose strain points are 511 and $570\ ^\circ\text{C}$, respectively (Figure 6). Since the relaxation rate is higher when the glass is heat treated at higher temperatures, thermal compaction becomes more important as the treatment temperature increases. Thermal compaction apparently decreases

Figure 6 Thermal compaction upon annealing near the glass transition range. Comparisons between the volumes of a soda-lime glass and a PDP substrate upon annealing (a) and upon reheating (b) after the annealing treatment shown in (a).

above $540\ ^\circ\text{C}$ for the soda-lime glass, however, simply because complete relaxation is achieved in this region that is close to the glass transition temperature of $550\ ^\circ\text{C}$. In other words, the soda-lime glass is no longer an elastic material and undergoes instead a permanent thermal deformation that spoils the panel fabricating process. Although the magnitude of thermal compaction increases at 550 – $600\ ^\circ\text{C}$ for the high-strain-point glass, the effect is not problematic for the process because it is homogeneous and reproducible upon well-controlled thermal conditions. In addition, it can be minimized by a two-step process whereby the glass is first heated in the glass transition range (Figure 6b). Such high-strain-point glass has thus enabled mass production of the large-sized PDPs with the required thermal stability.

Table 3 Chemical compositions (wt %) of frit glasses for PDP.

	Underlayer dielectric	Overlayer dielectric	Barrier rib	Pb-free barrier rib	Sealing
SiO ₂	28.4	8.0	37.2	11.2	3.3
Al ₂ O ₃		0.6	0.7		1.0
B ₂ O ₃	1.8	16.2		44.1	8.8
BaO					1.7
PbO	69.8	67.7	62.1		76.9
ZnO		7.5		41.2	10.0
Li ₂ O				3.5	
Softening point (°C)	576	471	580	533	372

3.3 Glass Frits

Glass frits are also important for realizing high-performance display devices. As described above, they were first used as a sealing glass in CRTs. They are still more important for PDPs where they serve to make key such parts as dielectric layers and barrier ribs (Table 3). They are printed on the glass substrate and patterned by sand blast or UV-lithography technologies before being fired at 500–600 °C and sealed with a glass similar to that used for CRTs. Their compositions have been optimized with regard to thermal expansion for thermal stability, absence of lead for environmental concerns, and low firing temperatures for economic reasons.

3.4 Front Cover Glass

Ever since the first smartphones were launched in the market in the early 2000s, a strong demand has manifested itself for tough, lightweight cover glasses. The main concerns were to ensure resistance to shocks (e.g. fall on the ground) and to prevent scratches from accumulating and making display reading difficult. Chemical tempering was the obvious solution because the process is not only the most efficient but also applicable to thin glass sheets as well as to products with a complex shape (Chapter 3.12). The appropriate surface compressive stress and the thickness of the ion-exchanged layer have been designed from fracture analyses [5] although a really fundamental understanding of stress generation and relaxation by ion exchange are still important issues [6]. As might be expected, these chemically tempered glasses are also used for tablet Cs and flat LCD TVs. Currently Corning, AGC, Nippon Electric Glass, and Schott AG are well-known companies that supply them.

3.5 Drivers: Glass for TFT Arrays

Drivers are electronic components controlling all elements of the displaying matrix device. They differ

depending on whether matrix addressing is passive or active although in both cases an $n \times m$ display is addressed by $m + n$ control signals. With a passive matrix, a pixel is maintained in the same state until it is refreshed; the drivers then are simply two series of electrodes lying at right angles on the glass substrate, which can be made of soda-lime glass. Commercial display devices usually rely instead on an active matrix, however, with which the state of each pixel is actively controlled by a thin-film transistor (TFT) and capacitor to avoid *crosstalk*, i.e. inadvertent pixel state changes, and, thus, to ensure a better picture quality.

These transistors are made of amorphous Si, polycrystalline Si, or oxide semiconductors such as In–Ga–Zn oxide as described in the literature [7, 8]. In the process, material deposition and etching are necessary steps because the gate bus lines, TFT channels, data lines, passivation, contact hole openings, and pixel electrodes are directly formed on the glass substrate. Hence the glass must be thermally and chemically stable at the temperatures and under the etching conditions relevant to the panel manufacture process. New glasses have thus been developed to satisfy these requirements through higher strain points and lower densities.

Thermal compaction is one of the factors that must be considered seriously. When the thin-film transistors of Liquid-Crystal Displays are made of amorphous silicon, the process temperatures of only 300–350°C [9] are unproblematic. Thermal compaction is, in contrast, a really critical issue when the thin-film transistors are made of polycrystalline silicon because much higher process temperatures of 550–600°C are then required. Some thin-films that include indium-tin-oxide (ITO) transparent electrodes are deposited and patterned on the glass substrate (Chapter 6.8). Mechanical properties, including easy scribing, are also an important issue for the glass substrates in the LCD and OLED panel manufacturing process [10] because multiple arrays formed on the substrate glass need to be separated correctly from one another.

Table 4 Properties of glass substrates for thin-film transistor liquid-crystal displays.

Company	Code	Density (g/cm ³)	Strain point (°C)	Thermal expansion (ppm/°C)	Young's modulus (GPa)	Data source

Avanstrate	NA32SG	2.41	661	3.45	73.9	Catalog

Historically, Corning #7059 glass was the first of such new glass substrates for TFT-LCDs [11]. Currently, Corning, AGC, Nippon Electric Glass, AvanStrate, and LG Chem are other companies that supply such glass substrates for TFT display devices (Table 4). Of particular importance is also a lack of fast-diffusing alkali ions (Chapters 4.2 and 4.3) in the composition. In LCD and OLED panels, the lifetime of TFTs would be shortened through damages caused by alkali intake by diffusion from the glass substrate. Likewise, alkali migration would also impair the electrodes of PDP panels. Alkali-free glasses based on boroaluminosilicate systems are thus commonly used in these cases. Since alkali elements are also the most efficient fluxes to lower liquidus and glass transition temperatures, their removal has in addition helped to improve mechanical properties and minimize thermal compaction during the high-temperature manufacturing steps.

4 Liquid-Crystal Displays

Originally the main limitation of CRTs was the maximum size of about 40 in. of the screens that could be made. As pioneered in the form of monitors in the computer industry, larger screens first relied on liquid-crystal technology, a new development that made use of the unusual optical properties of these phases first discovered in the case of cholesterol derivatives by the Austrian botanist Friedrich Reinitzer (1857–1927) in 1888 in Prague. At Reinitzer's request further observations were then made by Otto Lehman (1855–1922) in Aachen who found that these

crystals reflected circularly polarized light and rotated its polarization direction and also that they exhibited two melting points, first to a cloudy phase and then to a clear liquid. Work then made on the structure and properties of the great many new liquid crystals discovered showed in particular that their phase transitions could be induced by electric fields. These phases remained scientific curiosities, however, because of the temperatures significantly higher than 100 °C at which their phase transitions were taking place.

Display applications of liquid crystals thus awaited the synthesis of liquid crystals undergoing their phase transitions near room temperature. After a first patent for LCD was filed in 1962 in the United States for phase transitions still higher than 100 °C, much work was needed to achieve this goal [12]. Calculators with LCDs were eventually commercialized in 1973 in Japan where they were well received by the market. Another important milestone was the fabrication in Japan in 1984 of portable TVs with color LCDs of 2 in. in size. Thanks to rapid size increases, LCDs could then be used for the monitors of laptop PCs and TVs, while many new technologies were developed to ensure better image quality in particular through a higher resolution, wider viewing angles, and faster response times [13, 14].

In display applications, liquid crystals are either transparent or opaque under cross polarizers depending on the optical properties of the phases in which they have been locked in by an applied electrical field. All pixels are thus driven by distinct electrodes in a few μm thick cells sandwiched between two glass substrates (Figure 7) in which liquid crystals are inserted by vacuum suction. Since

Figure 7 Sketch of a liquid-crystal display. Alkali-free glasses are used for the front and back glasses, and indium-tin oxides for the transparent electrodes. The color filter is formed on the glass substrate from resin and organic or inorganic pigments. Like the liquid crystals, the polarizer, analyzer, orientation membrane, spacer, and liquid crystal are basically made from organic polymer materials.

liquid crystals are not light emissive, the display assembly must include a backlight in addition to the polarizer and analyzer. As the polarization angle of light from the backlight unit is changed by the arrangement of the liquid crystal, the intensity of the light that passes through the analyzer changes, so the brightness of each pixel is controlled. To create a color image, red, green, and blue color filters made of organic resin are formed as alternating vertical bands for each pixel on the front glass substrate. Owing to this complex structure, a low fraction of about 5% of the incident light is actually transmitted.

Many different configurations have been investigated to obtain a high picture quality through high response rates, wide viewing angles, and increased brightness. In an originally common configuration, two linear electrodes placed on the top and bottom of the glass surface create an electric field parallel to the glass plate to drive vertically the liquid-crystal transitions. In the more recent but more expensive *in-plane-switching* configuration, the liquid crystals align horizontally under a lateral electrical field applied between both of their ends to keep them parallel to the electrodes and the glass substrate so that they can move freely without being tied to the surface of the glass.

5 Plasma-Display Panels

The main reason why LCDs initially took over the market was a ready process scalability. But their refreshing rate is limited by relatively low phase transition kinetics, and they also suffer from a restricted contrast due to the

needed backlight, a real black hue being, for instance, impossible to obtain. When large-sized displays attracted a great interest in the late 1990s, it was commonly thought that PDPs were the only alternative because their simple structure was making their fabrication much easier than that of LCDs. Like fluorescent lamps (Chapter 6.9), PDPs rely on the light emitted by noble gases upon electrical discharges. The technology was first demonstrated in the United States in 1962. Applications to TV took a little while to be developed since color PDPs of 20 in. in size were made only in 1987 in Japan where 42 in. color screens then became commercially available in 1996, further efforts having been made to increase the size of TVs and improve their picture quality [15].

In PDPs, two glass substrates are sealed with a gap of about 200 μm (Figure 8) within which an inert gas, typically Xe, is enclosed. Individual pixels are defined by barrier ribs on the inside wall of which phosphors are deposited (Chapter 7.9). The light emitted by xenon is in the ultraviolet range when a discharge occurs between transparent ITO electrodes on the front glass. The function of the red, green, and blue phosphors is thus to emit a fluorescent visible light from the UV radiation of the gas to create a color image.

The dielectric layers and barrier ribs, which compose the unit cell of the PDPs, are formed on the glass substrates from a glass frit sintered at 500–600 $^{\circ}\text{C}$. Therefore, the thermal expansion coefficients of these materials have to match each other. In addition, the stability of the glass substrate against any thermal deformation must be minimized. Although normal soda-lime glass was used as a substrate during the initial stages of color PDPs, special compositions with high strain points have been developed and are now widely used to manufacture large-sized color PDPs (Table 5). These glasses were designed to have a CTE similar to that of soda-lime glass so that the same

Figure 8 Sketch of a plasma-display panel. High-strain-point glasses are used for the front and back glasses, and sintered glass frits for dielectric layers and barrier ribs. The transparent and address electrodes are usually made from indium-tin oxides and silver, respectively.

Table 5 Properties of glass substrates for plasma-display panels.

Company	Code	Density (g/cm ³)	Strain point (°C)	Thermal expansion (ppm/°C)	Young's modulus (GPa)	Data source
AGC	(Soda-lime glass)	2.49	511	8.5	72	Ref. [12]
	PD200	2.77	570	8.3	76	Ref. [12]
NEG	PP-8	2.82	582	8.3	77	Catalog

frit materials can be adopted. They are currently produced by companies like AGC and Nippon Electric Glass.

Generally, thermal compaction is higher for of PDP than for LCD glass because, as already noted, the process temperature of PDP is closer to the strain point of the material. However, the tolerances are also greater because PDPs are made only in large sizes for which the intrinsic resolution can be lower and, thus, cell sizes be bigger. The mechanical properties of the glass substrate are important issue for PDP as well as for TFT-LCD displays. Thermal shock failure was especially a serious problem in PDP fabrication because the CTE of PDP glass is much higher than that of TFT-LCD glass and also because the substrate is exposed many times to high temperatures [16].

6 Organic Light-Emitting Diodes

With respect to solid-state inorganic LEDs, OLEDs have the big advantage of making use of transparent semiconducting organic liquids, which makes in principle production of large light-emitting surfaces easy (Chapter 6.9). For display applications, additional advantages are high contrast and refreshing rates, thinner devices due to the need for single glass panel, and high energy efficiency because only the lit pixels consume energy. In 1987, a prototype OLED display was first demonstrated in the United States [17]. As early as 1997 a monochromatic OLED device was installed in car audio systems in Japan. In early 2000, color OLED devices began to be used for mobile displays such as smartphones. In contrast to LCDs, however, production scalability was not ready for OLED displays because of deposition and patterning difficulties. Commercial production of OLED TVs nonetheless began in 2007 with 11 in. screens in Japan. Since then, large-sized and high-resolution OLED TVs have been developed [18] and now strongly compete with LCD TVs in the market.

As described in more detail in Chapter 6.9, the main components of an OLED are a hole-injecting anode, the organic light emitter, an electron transportation layer,

Figure 9 Sketch of an organic light-emitting diode. Transparent electrode (ITO) and organic components deposited and patterned on the alkali-free glass substrate.

and an electron-injecting cathode deposited on the glass substrate (Figure 9). When a voltage is applied between the anode and cathode, holes and electrons are transferred to the organic layer where they form excitons that emit light when relaxing to the ground state of the valence band. Because OLEDs are driven by TFTs, substrates are basically made up of the same alkali-free glasses as those of LCDs. After all materials are deposited and patterned to make pixels on the glass substrate, they need to be encapsulated to be protected from moisture or oxygen attacks because most of organic materials in OLED devices are very weak against those gases.

7 Device Configuration

As illustrated by a smartphone configuration (Figure 1), many glass substrates having each function are combined in actual devices using FPDs. In LCDs, for example, a clear glass plate for guiding the backlight is used in addition to the front and back glasses. In all devices, a transparent touch sensor for human interfacing is now essential. In both the *resistive* and the *projective capacitive* touch sensors, which are two major technologies commonly used for handheld devices, glass is once more a fundamental element on which either electrodes or insulators are deposited, whose signal is then analyzed to locate the point of the screen that has been selected

Figure 10 Functions of the optical filter of a plasma-display panel.

by the user. And, as already described, the surface of the device is protected by a chemically tempered cover glass.

Finally, a few words must also be said about the typical optical filters used in PDP TVs (Figure 10). Their main purposes are (i) to calibrate color and (ii) to improve contrast. But they have many other functions, namely, (iii) to cut near-IR radiation to avoid interferences with other remote control units, (iv) to shield electromagnetic waves, (v) to be an antireflective layer (Chapter 6.8), (vi) to protect the panel from mechanical damage such as caused by impact, and (vii) to prevent smudge. Within the filter glass, a black mask is sometimes applied for decoration. Soda-lime glasses with some coatings and films are generally used to provide these functions.

8 Perspectives

The extremely strong and rapid decline of CRTs was not anticipated at all when flat displays appeared on the market in the late 1990s. Rather, it was thought that glass recycling would be the main issue [19, 20] to be solved adequately to keep their production going on. Likewise, the development of OLEDs has been much faster than expected. But it must also be stressed that all advances made in the last decades to switch from analog to digital image transmission would have been impossible without the availability of fast and cheap microprocessors and controllers to activate pixels whose numbers reach millions in the largest displays.

The size of current displays is now so large, and their resolution is so good that little room might seem to be left for real improvements in these respects. Building on the idea implemented in shopping malls or stadiums of giant displays made with usual LEDs, work is nonetheless done

to develop displays with pixel-sized, GaN-based micro-LEDs. The advantages would be a simpler structure (substrate, electrode, microLEDs, glass cover) and thus reduced thickness and weight, combined with further improvements in brightness, response times, energy efficiency, and lifetime, which would make these new displays especially valuable for smartphones or watches.

Guessing what additional advances might be made afterward is difficult. Since LEDs have been the last known source of light remaining to be exploited, some time will likely elapse before new devices are designed on a completely new basis. As illustrated by the *wind-screen* of cars (Chapter 9.2), a current trend is rather to include displays in an ever greater variety of devices and of settings. Another striking feature of the electronic revolution actually is the convergence that is making irrelevant to keep fundamental distinctions between TV sets, telephones, or cameras. Whether large or small, displays will thus be playing a fundamental role in all cases.

Volume I

General Introduction 1

Pascal Richet, Reinhard Conradt and Akira Takada

- 1 A Historical Random Walk 2
- 2 Some Basic Concepts of Glass Science 7

Section I. Glassmaking 23

1.1 Glass Production: An Overview 25

Reinhard Conradt

- 1 Introduction 25
- 2 Industrially Manufactured Glasses 26
- 3 Process-controlling Properties 28
- 4 Glass Composition – its Relevance to Glass Properties 34
- 5 Perspectives 36

1.2 Raw Materials for Glassmaking: Properties and Constraints 39

Simonpietro Di Pierro

- 1 Introduction 39
- 2 Raw-material Specifications 40
- 3 From Raw Materials to Melt 45
- 4 Special Raw Materials 48
- 5 Perspectives 50

1.3 Fusion of Glass 53

Reinhard Conradt

- 1 Introduction 53
- 2 Overview of Industrial Processes 54
- 3 Batch Preparation 54
- 4 The Conversion of Batch into Melt 57
- 5 Fining, Refining, Homogenization 62
- 6 Energetics of Glass Melting 63
- 7 Perspectives 64

1.4 Primary Fabrication of Flat Glass 67

Toru Kamihori

- 1 Introduction 67
- 2 Overview 68
- 3 Updraw Processes 70
- 4 Roll Out Process 71
- 5 Float Process 72
- 6 Downdraw Processes 77
- 7 Perspectives 78

1.5 Fabrication of Glass Containers 81*Christian Roos*

- 1 Introduction 81
- 2 Principles of Glass-Container Forming 82
- 3 Glass-Container Forming Processes 84
- 4 Making of the Gob: Forehearth, Feeder, and Shears 87
- 5 IS-Forming Machine 88
- 6 Hot-End Handling, Hot-End Coating, and Annealing 91
- 7 Cold-End Handling and Inspection 91
- 8 Perspectives 92

1.6 Continuous Glass Fibers for Reinforcement 95*Hong Li and James C. Watson*

- 1 Introduction 95
- 2 Commercial Glass Fibers 95
- 3 Manufacturing of Glass Fibers 100
- 4 Markets and Applications 106
- 5 Perspectives 108

1.7 Simulation in Glass Processes 111*Patrick J. Prescott and Bruno Purnode*

- 1 Introduction 111
- 2 A Brief Overview 111
- 3 Fundamental Phenomena, Governing Equations, and Simulation Tools 113
- 4 Simulations in Glass Manufacturing Processes: A Few Examples 117
- 5 Simulation Data Management 123
- 6 Perspectives 125

Section II. Structure 127**2.1 Basic Concepts of Network Glass Structure 129***Alex C. Hannon*

- 1 Introduction 129
- 2 The Zachariasen–Warren Random Network Model 130
- 3 Silica – The Archetypal Glass 131
- 4 Microcrystalline Models 133
- 5 Modifiers and Non-Bridging Oxygens 133
- 6 Intermediate-Range Order 137
- 7 Chalcogenide Glasses 138
- 8 Perspectives 139

2.2 Structural Probes of Glass 141*Grant S. Henderson*

- 1 Introduction 141
- 2 Diffraction (Scattering) 143
- 3 X-ray Absorption Techniques 147
- 4 Nuclear Magnetic Resonance Spectroscopy 149
- 5 Vibrational Spectroscopies 151
- 6 Other Techniques 155
- 7 Perspectives 157

2.3 Microstructure Analysis of Glasses and Glass Ceramics 159*Christian Patzig and Thomas Höche*

- 1 Introduction 159
- 2 Scanning Electron Microscopy 160
- 3 Transmission Electron Microscopy 163
- 4 Scanning Probe Microscopy 168
- 5 X-Ray Microscopy 170
- 6 Perspectives 170

- 6 Glass Transition and Thermodynamic Scaling 509
- 7 Perspectives 509

Section V. Chemistry of Glass 511**5.1 Chemical Analyses and Characterization of Glass 515***Thomas Bach, Reiner Haus and Sebastian Prinz*

- 1 Introduction 515
- 2 Gravimetry and Glass Digestion 517
- 3 X-Ray Fluorescence 517
- 4 Inductively Coupled Plasma Methods 518
- 5 Atomic Absorption Spectroscopy 520
- 6 Microprobe Analyses 521
- 7 Special Elements 521
- 8 Resistance to Chemical Attack 523
- 9 Analyses of Glass Defects 525
- 10 Perspectives 525

5.2 Phase Equilibria and Phase Diagrams in Oxide Systems 529*Ilya Veksler*

- 1 Introduction 529
- 2 Thermodynamic Principles 530
- 3 Basic Topological Types of Binary T - x Diagrams 532
- 4 Ternary Diagrams 537
- 5 Some Phase Diagrams for Glass-Forming Systems 538
- 6 Perspectives 541

5.3 Thermodynamic Models of Oxide Melts 545*Giulio Ottonello*

- 1 Introduction 545
- 2 General Considerations 546
- 3 Thermodynamic Models 548
- 4 First-Principles Calculations 555
- 5 Perspectives 556

5.4	Nucleation, Growth, and Crystallization in Inorganic Glasses	559
	<i>Edgar D. Zanotto, Jörn W. P. Schmelzer and Vladimir M. Fokin</i>	
1	Introduction	559
2	Crystal Nucleation and Classical Nucleation Theory	560
3	Basic Models of Crystal Growth in Supercooled Liquids	564
4	Overall Crystallization and Glass-forming Ability: The Johnson–Mehl–Avrami–Kolmogorov Approach	565
5	Perspectives	567
5.5	Solubility of Volatiles	571
	<i>Bjorn Mysen</i>	
1	Introduction	571
2	Principles and Concepts	571
3	Reactive Volatiles in Silicate Glass and Melt	573
4	Nonreactive Volatiles in Silicate Glass and Melt	578
5	Perspectives	579
5.6	Redox Thermodynamics and Kinetics in Silicate Melts and Glasses	581
	<i>Reid F. Cooper</i>	
1	Introduction	581
2	Oxidation/Reduction Thermodynamics	581
3	Oxidation/Reduction Kinetics	586
4	Open-System Redox Dynamics	586
5	Closed-System (or Internal) Redox Dynamics	593
6	Perspectives	595
5.7	Optical Basicity: Theory and Application	597
	<i>John A. Duffy</i>	
1	Introduction: The Need for a Suitable Basicity Scale for Oxide Melts	597
2	Theoretical Foundation of Optical Basicity	597
3	Redox Equilibria in Network Melts	600
4	Optical Basicity and Electronic Polarizability	601
5	Chemical Reactions: Changes in Structure and Bonding	601
6	High and Low Optical–Basicity Materials	604
7	Optical Basicity and Electronegativity	604
8	Perspectives	606
5.8	The Glass Electrode and Electrode Properties of Glasses	609
	<i>Anatolii A. Belyustin and Irina S. Ivanovskaya</i>	
1	Introduction	609
2	Types and Properties of Glass Electrodes	610
3	Glass Structure as Viewed by the Glass Electrode	612
4	Theories of the Glass Electrode	614
5	Perspectives	616
5.9	Electrochemistry of Oxide Melts	619
	<i>Christian Rüssel</i>	
1	Introduction	619
2	Thermodynamics of Redox Equilibria	619
3	Experimental Aspects	620
4	Standard Potentials and Equilibrium Constants	621
5	Diffusion Coefficients	623
6	Voltammetric Sensors: Quantitative Determinations of Polyvalent Elements	624
7	Impedance Spectroscopy	625
8	Perspectives	626
5.10	Glass/Metal Interactions	629
	<i>Carine Petitjean, Pierre-Jean Panteix, Christophe Rapin, Michel Vilasi, Eric Schmucker and Renaud Podor</i>	
1	Introduction	629
2	Wetting, Sticking, and Adhesion Phenomena	629

- 3 Control of High-Temperature Chemical Interactions at the Metal/Molten Glass Interface 631
- 4 Characterization of the Glass/Metal Interaction 632
- 5 Corrosion of Metals and Alloys by Molten Glass 635
- 6 Perspectives 638

5.11 Durability of Commercial-type Glasses 639

Marie-Hélène Chopinet, Hervé Montigaud, Patrice Lehuédé and Sylvie Abensour

- 1 Introduction 639
- 2 Chemical Processes and Parameters 639
- 3 Alteration as Related to Glass Composition 641
- 4 Post-Production Corrosion of Flat and Container Glass 642
- 5 Characterization Methods 644
- 6 Protection Methods 645
- 7 Perspectives 645

5.12 Mechanisms of Glass Corrosion by Aqueous Solutions 647

Roland Hellmann

- 1 Introduction 647
- 2 Early Models 648
- 3 Leached-layer Model 648
- 4 Coupled Interfacial Dissolution-Reprecipitation (CIDR) 652
- 5 Rates of Dissolution and Element Release 657
- 6 Perspectives 660

Section VI. Glass and Light 663

6.1 Optical Glasses 665

Alix Clare

- 1 Introduction 665
- 2 Basic Features 666
- 3 Transmitted Light T_{in} 667
- 4 Glass Properties 670
- 5 Glass Responses 671
- 6 Interaction of Optical Components with Light 673
- 7 Perspectives 674

6.2 The Color of Glass 677

Georges Calas, Laurence Galois and Laurent Cormier

- 1 Introduction 677
- 2 Background on Color Processes 677
- 3 Crystal-Field-Driven Glass Color 681
- 4 Variation of Glass Coloration 685
- 5 Temperature Dependence of the Optical Absorption Spectra of Glasses: Thermochromism 687
- 6 Charge-Transfer Processes: From Amber Glasses to Lunar Glasses 688
- 7 Absorption by Organized Clusters and Nanophases 689
- 8 Perspectives 690

6.3 Photoluminescence in Glasses 693

Lothar Wondraczek

- 1 Introduction 693
- 2 Inelastic Light Scattering Through Photoluminescence 694
- 3 Photoluminescence and Glass Chemistry 697
- 4 Efficiency, Lifetime, and Quenching Effects 700
- 5 Applications 701
- 6 Perspectives 702

6.4 Optical Fibers 705

John Ballato

- 1 Introduction 705
- 2 Optical Properties and Fiber Designs 706

3	Optical Fiber Glasses	711
4	Optical Fiber Fabrication	714
5	Applications	718
6	Perspectives	718
6.5	Fluoride and Chalcogenide Glasses for Mid-infrared Optics	721
	<i>Bruno Bureau and Jacques Lucas</i>	
1	Introduction	721
2	Glass Transparency in the Infrared Region	721
3	Fluoride Glasses: Formation and Structure	723
4	Applications of Fluoride Glasses	724
5	Chalcogenide Glasses	726
6	Chalcogenide Glass Applications	730
7	Perspectives	732
6.6	Optoelectronics: Active Chalcogenide Glasses	735
	<i>Jong Heo and Kai Xu</i>	
1	Introduction	735
2	Active Chalcogenide Glasses Doped with Rare-Earth Ions	735
3	Optical Fiber Amplifiers	736
4	Mid-Infrared Lasers	739
5	Chalcogenide Quantum Dots	743
6	Perspectives	747
6.7	Modification Technologies of Glass Surfaces	751
	<i>İlkay Sökmen, Sener Oktik and Klaus Bange</i>	
1	Introduction	751
2	Hot-End Processes in Glass Production	752
3	Cleaning	754
4	Strengthening	756
5	Modification of the Surface Topography	757
6	Structuring and Texturing	757
7	Applications	758
8	Perspectives	760
6.8	Thin-Film Technologies for Glass Surfaces	763
	<i>Sener Oktik, İlkay Sökmen and Klaus Bange</i>	
1	Introduction	763
2	Deposition Techniques	764
3	Thin Films	766
4	Transparent Conducting Oxides	767
5	Miscellaneous Uses	772
6	Perspectives	772
6.9	Glass for Lighting	775
	<i>Hiroki Yamazaki and Shigeru Yamamoto</i>	
1	Introduction	775
2	Glass for Incandescent and Electric Discharge Lamps	776
3	Glass for Solid-State Lighting	781
4	Perspectives	784
6.10	Screens and Displays	787
	<i>Kei Maeda</i>	
1	Introduction	787
2	Cathode-Ray Tubes	788
3	Glasses for Flat-Panel Displays	790
4	Liquid-Crystal Displays	793
5	Plasma-Display Panels	794

- 6 Organic Light-Emitting Diodes 795
- 7 Device Configuration 795
- 8 Perspectives 796

Volume II

Section VII. Inorganic Glass Families 799

7.1 Extraterrestrial Glasses 801

Guy Libourel

- 1 Introduction 801
- 2 Chondrules: The Oldest Glasses of the Solar System 802
- 3 The Lunar Glass-Bead Factory 805
- 4 Cosmic Spherules 808
- 5 Terrestrial Versus Extraterrestrial 810
- 6 Perspectives 811

7.2 Geological Glasses 815

Cristina P. De Campos and Kai-Uwe Hess

- 1 Introduction 815
- 2 Compositional Diversity of Natural Glasses 815
- 3 Fulgurites: The Petrified Lightnings 817
- 4 Impact-Related Glasses 817
- 5 The Basalt Factory 820
- 6 Siliceous Glasses 822
- 7 The Fate of Natural Glasses 825
- 8 Compositional vs. Rheological Variability 826
- 9 Perspectives 828

7.3 Corrosion of Natural Glasses in Seawater 831

Roland Hellmann

- 1 Introduction 831
- 2 From Basalt Glass to Palagonite 831
- 3 Seafloor Basalt Alteration by Abiotic and Biotic Processes 832
- 4 Alteration Enhancement by Microorganism Metabolic Processes 832
- 5 Biotic Corrosion Models 833
- 6 Abiotic Corrosion Models 836
- 7 The Abiotic vs. Biotic Alteration Debate 838
- 8 Which Mechanism Controls Basalt Glass Corrosion? 839
- 9 Perspectives 840

7.4 Metallurgical Slags 843

Kenneth C. Mills

- 1 Introduction 843
- 2 Basic Constraints: A Summary 844
- 3 From Composition to Reactivity 846
- 4 Slag Properties 847
- 5 Transport Properties 849
- 6 Thermodynamic Properties 853
- 7 Perspectives 854

7.5 Water Glass 857

Hans Roggendorf

- 1 Introduction 857
- 2 Fabrication of Water Glass 857
- 3 Materials and Chemical Stability and Structure 859
- 4 Properties of Water Glass 863
- 5 Applications of Water Glass 863
- 6 Perspectives 864

7.6 Borosilicate Glasses 867*Randall E. Youngman*

- 1 Introduction 867
- 2 Borosilicate Applications 867
- 3 Vycor: A Composition–Structure Case Study 870
- 4 Structural Aspects 871
- 5 Temperature and Pressure Variations of Network Structure 874
- 6 Perspectives 876

7.7 Glass for Pharmaceutical Use 879*Daniele Zuccato and Emanuel Guadagnino*

- 1 Introduction 879
- 2 Glass Products and Types 879
- 3 Production of Pharmaceutical Glasses and Containers 880
- 4 Physical Resistance 882
- 5 Chemical Resistance 883
- 6 Surface Interactions with Pharmaceutical Products 885
- 7 Internal/External Treatments for Chemical/Mechanical Resistance 887
- 8 Perspectives 888

7.8 Oxynitride Glasses 891*Stuart Hampshire and Michael J. Pomeroy*

- 1 Introduction 891
- 2 Solubility of Nitrogen in Glasses 891
- 3 Glass Formation in M–Si–Al–O–N Systems and Its Representation 892
- 4 Structure of Oxynitride Glasses 893
- 5 Effects of Composition on Properties 895
- 6 Oxynitride Glass–Ceramics 898
- 7 Phosphorus Oxynitride Glasses 899
- 8 Lower-Temperature Preparation Methods 899
- 9 Perspectives 899

7.9 Phosphate Glasses 901*Andrew James Parsons*

- 1 Introduction 901
- 2 Structure 902
- 3 Synthesis 904
- 4 Physical Properties 906
- 5 Optical Properties 908
- 6 Chemical Properties 911
- 7 Other Applications 914
- 8 Perspectives 914

7.10 Bulk Metallic Glasses 919*Dmitri V. Louzguine-Luzgin and Akihisa Inoue*

- 1 Introduction 919
- 2 Glass Formation 920
- 3 Structure 923
- 4 Mechanical Properties 925
- 5 Deformation Behavior at Room Temperature 927
- 6 Magnetism: Properties and Applications 931
- 7 Other Properties and Applications 932
- 8 Perspectives 934

7.11 Glass-Ceramics 937*Monique Comte*

- 1 Introduction 937
- 2 History and Present Uses of Glass-Ceramics 937

- 3 Properties of Glass-Ceramics 943
- 4 Examples of Glass-Ceramics 945
- 5 Perspectives 949

Section VIII. Organically Related Glasses 951

8.1 Biogenic Silica Glasses 955

Jacques Livage and Pascal Jean Lopez

- 1 Introduction 955
- 2 A Slowly Awakening Scientific Interest 956
- 3 Biogenic Silica 958
- 4 The Low-Temperature Silica Factories 962
- 5 Biomimetism and Applications 963
- 6 Biogenic Silica in the Global Ecosystem 964
- 7 Perspectives 964

8.2 Sol–Gel Process and Products 969

Rui M. Almeida and M. Clara Gonçalves

- 1 Introduction 969
- 2 Sol–Gel Processing 970
- 3 Advantages and Drawbacks of the Sol–Gel Process 974
- 4 Sol–Gel Products and Applications 974
- 5 Perspectives 978

8.3 Silica Aerogels 981

Wim J. Malfait, Jannis Wernery, Shanyu Zhao, Samuel Brunner, and Matthias M. Koebel

- 1 Introduction 981
- 2 Synthesis 982
- 3 Properties 983
- 4 Applications 986
- 5 Markets and Industrial Production 986
- 6 Silica Hybrid Aerogels, Aerogel Composites, and Non-silica Aerogels 988
- 7 Perspectives 988

8.4 Bioactive Glasses 991

Delia S. Brauer and Julian R. Jones

- 1 Introduction 991
- 2 Melt-Derived Bioactive Glasses 991
- 3 Bioactive Sol–Gel Glasses 993
- 4 Degradation and Apatite Formation 994
- 5 Biological Response 996
- 6 Therapeutic Ions in Bioactive Glasses 997
- 7 Applications of Bioglasses 998
- 8 Perspectives 1001

8.5 Dental Glass-Ceramics 1005

Wolfram Höland and Marcel Schweiger

- 1 Introduction 1005
- 2 History and Present Uses of Dental Glass-Ceramics 1006
- 3 Properties of Dental Glass-Ceramics 1006
- 4 Examples of Dental Glass-Ceramics 1007
- 5 Perspectives 1010

8.6 Relaxation Processes in Molecular Liquids 1013

Thomas Blochowicz, Ernst A. Rössler and Michael Vogel

- 1 Introduction 1013
- 2 From the Boiling Point Down to the Glass Transition 1015
- 3 Binary Glass-Forming Liquids 1021
- 4 Secondary Relaxations 1024

5 Plastic and Glassy Crystals 1026

6 Perspectives 1027

8.7 Physics of Polymer Glasses 1031

Jean-Pierre Cohen-Addad

1 Introduction 1031

2 Polymeric Chains 1032

3 Polymeric Liquids 1033

4 Polymer Transformations 1036

5 Glass Transitions and Aging 1036

6 Polymer Products 1039

7 Perspectives 1040

8.8 Introduction to Polymer Chemistry 1043

Oliver Weichold

1 Introduction 1043

2 Polymer Synthesis 1045

3 Polymerization Processes 1050

4 The Solid State 1052

5 Perspectives 1054

8.9 Hybrid Inorganic–Organic Polymers 1057

Karl-Heinz Haas and Gerhard Schottner

1 Introduction 1057

2 Sol–Gel for Hybrid Materials 1057

3 Coatings 1061

4 Particles 1065

5 Bulk Materials, Fibers, and Composites 1065

6 Perspectives 1066

Section IX. Environmental and Other Issues 1069

9.1 Structural Glass in Architecture 1071

Freek Bos and Christian Louter

1 Introduction 1071

2 Scheme Design 1071

3 Float-Glass Processing for Structural Applications 1074

4 Design and Detailing 1077

5 Connections 1079

6 Perspectives 1083

9.2 Tempered and Laminated Glazing for Cars 1091

René Gy

1 Introduction 1091

2 A Brief History from the Early Twentieth Century to Today's Huge Market 1091

3 Glazing Functions 1092

4 Manufacturing 1097

5 Perspectives 1101

9.3 Stone and Glass Wool 1103

Yuanzheng Yue and Mette Solvang

1 Introduction 1103

2 Classification of Man-Made Vitreous Wool 1104

3 Fiber Spinning Technologies 1104

4 Melt Viscosity and Fiber Spinnability 1106

5 Physical Properties of Stone and Glass Wool 1108

6 Biopersistence and Biodurability 1110

7 Perspectives 1111

9.4 Glasses for Solar-energy Technologies 1113*Joachim Deubener and Gundula Helsch*

- 1 Introduction 1113
- 2 The Energy Problem 1113
- 3 Solar Electricity 1114
- 4 Solar Heat 1117
- 5 Solar Fuels 1120
- 6 Solar Water Treatments 1121
- 7 Perspectives 1122

9.5 Sulfide-glass Electrolytes for All-solid-state Batteries 1125*Akitoshi Hayashi and Masahiro Tatsumisago*

- 1 Introduction 1125
- 2 Classification of All-solid-state Batteries 1126
- 3 Sulfide Glasses 1127
- 4 Sulfide Glasses as Solid Electrolytes 1128
- 5 Bulk-type Batteries with Sulfide Electrolytes 1130
- 6 Interfacial Design 1131
- 7 Perspectives 1133

9.6 The World of the Flat-glass Industry: Key Milestones, Current Status, and Future Trends 1135*Bernard J. Savaète*

- 1 Introduction 1135
- 2 A Short Overview: Processes and Products 1135
- 3 The Float-glass World 1139
- 4 Perspectives 1145

9.7 Design and Operation of Glass Furnaces 1147*Christoph Jatzwauk*

- 1 Introduction 1147
- 2 The Furnace Families 1148
- 3 Melter 1152
- 4 Heat Management 1155
- 5 Furnace Design 1159
- 6 NO_x Emissions 1161
- 7 Perspectives 1162

9.8 Physics and Modeling of Glass Furnaces 1165*Reinhard Conradt and Erik Muijsenberg*

- 1 Introduction 1165
- 2 Furnace Parameters 1166
- 3 The Physics of Glass Furnaces 1166
- 4 Modeling of Glass Furnaces 1173
- 5 Perspectives 1176

9.9 Glass Cullet: Sources, Uses, and Environmental Benefits 1179*Nicola Favaro and Stefano Ceola*

- 1 Introduction 1179
- 2 Basic Features of Cullet 1180
- 3 Glass Recycling 1182
- 4 Separation Technologies 1184
- 5 Miscellaneous 1186
- 6 Environmental Aspects 1187
- 7 Perspectives 1188

9.10 Immobilization of Municipal and Industrial Waste 1191*Soraya Heuss-Aßbichler and Athanasius P. Bayuseno*

- 1 Introduction 1191

2	Municipal Solid Waste Incineration Residues	1192
3	Environmental Impact of MSWI Residues	1199
4	Special Residues	1201
5	Perspectives	1203
9.11	Nuclear Waste Vitrification	1205
	<i>Olivier Pinet, Etienne Vernaz, Christian Ladirat, and Stéphane Gin</i>	
1	Introduction	1205
2	History of Nuclear Waste Vitrification	1205
3	Nuclear Glasses	1206
4	Long-Term Stability of Nuclear Glass	1209
5	Industrial Implementation of Nuclear Waste Vitrification	1213
6	Perspectives	1217
9.12	The International Commission on Glass (ICG)	1219
	<i>John M. Parker</i>	
1	Introduction: Origins of ICG and Founding Members	1219
2	ICG as an Organization	1219
3	The ICG Committees	1222
4	Public Activities	1223
5	Perspectives	1228
Section X. History 1231		
10.1	Obsidian in Prehistory	1237
	<i>Robert H. Tykot</i>	
1	Introduction	1237
2	Geological Formation, Properties, and Sources	1238
3	Obsidian Use in Prehistory	1238
4	Obsidian Studies	1240
5	Provenance Analysis Methods	1241
6	The Issue of Obsidian Sources: The European Region	1243
7	Obsidian Artifacts Studied in the Western Mediterranean	1243
8	Obsidian Trade and Socioeconomic Systems	1245
9	Conclusions and Closing Perspectives	1247
10.2	Ancient Glass, Late Bronze Age	1249
	<i>Andrew J. Shortland and Patrick Degryse</i>	
1	Introduction	1249
2	Early Glass: From Faience to Glassmaking	1250
3	Chemical Composition: The Analytical Standpoint	1251
4	Material Sources	1254
5	The Issue of Provenance	1255
6	The Isotopic Clues	1256
7	Perspectives	1258
10.3	Roman Glass	1261
	<i>Ian C. Freestone</i>	
1	Introduction	1261
2	Glass Synthesis	1261
3	Provenance and Location of Glassmaking	1263
4	Color Generation and Control	1265
5	Secondary Production and Consumption	1267
6	Recycling, Shifts in Production, and Decline	1269
7	Perspectives	1270
10.4	Glass and the Philosophy of Matter in Antiquity	1273
	<i>Marco Beretta</i>	
1	Introduction	1273
2	Near Eastern Views on Glass	1273

- 3 The Glass of the Greek Philosophers 1275
- 4 Glass and Alchemy 1276
- 5 The Byzantine Connection 1280
- 6 Perspectives 1282

10.5 Ancient Glassworking 1285

E. Marianne Stern

- 1 Introduction 1285
- 2 Basic Features of Glass Shaping 1286
- 3 Early Shaping Methods 1288
- 4 The Slow Blowing Revolution 1295
- 5 Decoration 1297
- 6 Special Techniques 1299
- 7 Secondary Glassworking 1302
- 8 A Short Retrospective Overview 1304
- 9 Perspectives 1305

10.6 Glazes and Enamels 1309

Philippe Colomban

- 1 Introduction 1309
- 2 Preparation and Thermal Constraints 1311
- 3 Composition and Microstructure 1312
- 4 Coloration 1316
- 5 Enamels 1320
- 6 Glazes 1322
- 7 Perspectives 1324

10.7 Venetian Glass 1327

Marco Verità

- 1 Introduction 1327
- 2 Raw Materials and Glassmaking 1328
- 3 The Origins of Venetian Glass 1329
- 4 Venetian Renaissance Glass 1331
- 5 *Façon de Venise* Glass and Competition 1337
- 6 Other Italian Glassmaking Traditions 1337
- 7 Perspectives 1338

10.8 Stained Glass Windows 1341

John M. Parker and David Martlew

- 1 Introduction 1341
- 2 Making Glass Sheets 1342
- 3 Social Context 1346
- 4 Glass Decoration 1348
- 5 Leading 1352
- 6 Later Trends: Nineteenth to Twentieth Century 1354
- 7 Conservation 1356
- 8 Perspectives 1357

10.9 Furnaces and Glassmaking Processes: From Ancient Tradition to Modernity 1361

Marie-Hélène Chopinet and Pascal Richet

- 1 Introduction 1361
- 2 The Written Sources 1362
- 3 Furnaces 1364
- 4 Plate Glass 1372
- 5 Container Glass 1375
- 6 Perspectives 1381

10.10 Glass, the Wonder Maker of Science 1387

Pascal Richet

- 1 Introduction 1387

- 2 The Source of Optics 1388
- 3 The Enabler of Chemistry 1395
- 4 Hotness and Air Weight Measured 1399
- 5 From Electrostatics to Subatomic Physics 1404
- 6 Perspectives 1408

10.11 A History of Glass Science 1413

Pascal Richet

- 1 Introduction 1413
- 2 Glass: An Impossible Definition? 1414
- 3 The Origins 1415
- 4 The Early Modern Period (Sixteenth to Eighteenth Centuries) 1418
- 5 The Chemical Revolution 1420
- 6 The Crystal Connection 1421
- 7 The Multiple Roots of Glass Science 1423
- 8 Perspectives 1433

10.12 Glass Museums 1441

Dedo von Kerssenbrock-Krosigk

- 1 Introduction 1441
- 2 The Invention of the Glass Museum 1442
- 3 Glass Museums 1443
- 4 Types of Glass Collections 1443
- 5 The Corning Museum of Glass 1450
- 6 Glass Museums: Purpose and Concerns 1451
- 7 Perspectives 1452

11.1 Postface – A Personal Retrospective 1457

C. Austen Angell

Subject Index 1463

Name Index 1489

List of Contributors

Functions and affiliations at the time of publication of the *Encyclopedia*

Abensour, Sylvie

Analytical Chemistry Group Manager
Expertise Department on Crystalline and Composite Materials,
Saint-Gobain Research Paris
39 Quai Lucien Lefranc, 93300 Aubervilliers, France
– 5.11: Durability of Commercial-type Glasses.

Almeida, Rui M.

Catedrático, Departamento de Engenharia Química, CQE
Instituto Superior Técnico
Universidade de Lisboa
Av. Rovisco Pais 1049-001 Lisboa, Portugal
– 8.2: Sol-gel Processes and Products.

Angell, C. Austen

Regent's Professor, School of Molecular Sciences
Arizona State University Tempe, AZ 85287-1604, USA
– 11.1: Postface – A Personal Retrospective.

Bach, Thomas

Head of Laboratory, Dorfner Analysenzentrum und
Anlagenplanungsgesellschaft mbH (ANZAPLAN)
Scharhof 1, 92242 Hirschau, Germany
– 5.1: Chemical Analyses and Characterization of Glass.

Ballato, John, J. E.

Sirrine Endowed Chair in Optical Fiber, and Professor
Department of Materials Science and Engineering and the Center
for Optical Materials Science and Engineering Technologies
(COMSET)
Clemson University, Clemson SC 29631, USA
– 6.4: Optical Fibers.

Bange, Klaus

Consultant, MK Consulting GmbH, Burgunderstr. 8, 55270
Jugenheim, Germany
– 6.7: Modification Technologies of Glass Surfaces;
6.8: Thin-Film Technologies for Glass Surfaces.

Bayuseno, Athanasius P.

Professor, Centre for the Waste Management
Department of Mechanical Engineering
Diponegoro University, Tembalang Campus Semarang 50275,
Indonesia
– 9.10: Immobilization of Municipal and Industrial Waste.

Belyustin, Anatolii A. (deceased)

Former Professor of Physical Chemistry, Chemistry Institute c/o
Saint Petersburg State University Physical Chemistry Department,
Saint Petersburg State University, Universitetskii prospect, 26,
Petrodvorets
198504 Saint Petersburg, Russia
– 5.8: The Glass Electrode and Electrode Properties
of Glasses.

Beretta, Marco

Professor of History of Science
Dipartimento di Filosofia e Comunicazione
Università di Bologna, via Zamboni 38, 40126 Bologna, Italy
– 10.4: Glass and the Philosophy of Matter in Antiquity.

Blochowitz, Thomas

Privatdozent, Institut für Festkörperphysik
Technische Universität Darmstadt, Hochschulstraße 6-8
64289 Darmstadt, Germany
– 8.6: Relaxation Processes in Molecular Liquids.

Bos, Freek

Assistant Professor Concrete Structures
Unit Structural Design, Department of the Built Environment,
Eindhoven University of Technology (TU/e), PO Box 513, 5600 MB
Eindhoven
The Netherlands
– 9.1: Structural Glass in Architecture.

Brauer, Delia S.

Professor for Bioactive Glasses
Otto Schott Institute of Materials Research
Friedrich Schiller University Jena
Fraunhoferstr. 6, 07743 Jena, Germany
– 8.4: Bioactive Glasses.

Brunner, Samuel

Research Scientist, Laboratory for Building Energy Materials and
Components, EMPA
Überlandstrasse 129, 8600 Dübendorf Switzerland
– 8.3: Silica Aerogels.

Bureau, Bruno

Professor, Université de Rennes I, Verres et Céramiques
Institut des Sciences Chimiques, UMR-CNRS 6226
35700 Rennes, France
– 6.5: Fluoride and Chalcogenide Glasses for
Mid-infrared Optics.

Calas, Georges

Professor, Institut de Mineralogie, de Physique des Matériaux et de Cosmochimie, Sorbonne Université
UMR CNRS 7590, Muséum National d'Histoire Naturelle, IRD, 4
Place Jussieu 75005 Paris, France
– 6.2: The Color of Glass.

Ceola, Stefano

Researcher, Stazione Sperimentale del Vetro
Via Briati 10, 30141 Venice, Italy
– 9.9: Glass Cullet: Sources, Uses, and Environmental Benefits.

Chopinnet, Marie-Hélène

Former Senior Research Engineer
Saint-Gobain Research Paris, 90 rue Duhesme
75018 Paris, France
– 5.11: Durability of Commercial-type Glasses; 10.9: Furnaces and Glassmaking Processes: From Ancient Tradition to Modernity.

Clare, Alix

Professor, Kazuo Inamori School of Engineering
Alfred University, Alfred, NY 14802, USA
– 6.1: Optical Glasses.
Cohen-Addad, Jean-Pierre (deceased)
Former Professor, Laboratoire LiPhy
Université J. Fourier, Grenoble
38402 Saint-Martin d'Hères, France
– 8.7: Physics of Polymer Glasses.

Colomban, Philippe

Emeritus Research Director, CNRS
Laboratory "From Molecule to Nano-object: Reactivity,
Interaction & Spectroscopies," Sorbonne Universités, 4 place
Jussieu, 75252 Paris Cedex 05, France
– 10.6: Glazes and Enamels.

Comte, Monique

Research Engineer, Advanced Materials Research Group, Corning
European Technology Center
Corning SAS, 77210 Avon, France
– 7.11: Glass-Ceramics.

Conradt, Reinhard

Uniglass AC GmbH, Nizzaallee 75
52072 Aachen, Germany, President
Deutsche Glastechnische Gesellschaft
Former Professor of Glass and Ceramic Composites
RWTH Aachen University, Aachen 52072, Germany
– General Introduction; 1.1: Glass Production: An Overview; 1.3:
Fusion of Glass; 9.8: Physics and Modeling of Glass Furnaces.

Cooper, Reid F.

Professor, Department of Earth, Environmental and Planetary
Sciences, Brown University, Box 1946, Providence RI 02912, USA
– 5.6: Redox Thermodynamics and Kinetics in Silicate
Melts and Glasses.

Cormier, Laurent

Research Director, Institut de Mineralogie
de Physique des Matériaux et de Cosmochimie
Sorbonne Université, UMR CNRS 7590, Muséum National
d'Histoire Naturelle, IRD, 4 Place Jussieu
75005 Paris, France
– 6.2: The Color of Glass.

de Campos, Cristina P., Visiting Professor
Earth and Environmental Sciences
Ludwig-Maximilians-Universität LMU
Theresienstr. 41/III Munich 80333, Germany
– 7.2: Geological Glasses.

Degryse, Patrick

Professor, Department of Earth and Environmental Sciences –
Geology, Center for Archaeological Sciences
KU Leuven, Celestijnenlaan 200E
Box 2408, BE-3001, Leuven
Belgium and Faculty of Archaeology
Universiteit Leiden, Leiden
the Netherlands
– 10.2: Ancient Glass Late Bronze Age.

de Koker, Nico

Research Fellow, Department of Civil Engineering
University of Stellenbosch, 7600, South Africa
– 4.3: Diffusion in Oxide Glass-forming Systems.

de Ligny, Dominique

Chair of Glass and Ceramics
Department of Materials Science and Engineering
Friedrich Alexander Universität Erlangen-Nürnberg
Martensstr. 5, 91058 Erlangen, Germany
– 3.6: Thermodynamic Properties of Oxide Glasses and Liquids.

Deubener, Joachim

Professor of Glass Science and Engineering
Institute of Non-Metallic Materials
Clausthal University of Technology
38678 Clausthal-Zellerfeld, Germany
– 4.1: Viscosity of Glass-forming Melts;
9.4: Glass for Solar-energy Technologies.

Di Piero, Simonpietro

Director, Expertise Department on Crystalline and Composite
Materials, Saint-Gobain Research Paris
39 Quai Lucien Lefranc
93300 Aubervilliers, France
– 1.2: Raw Materials for Glass Making: Properties and Constraints.

Duffy, John A. (deceased)

Former Emeritus Professor of Chemistry
University of Aberdeen, Old Aberdeen
AB24 3UE Scotland, UK
– 5.7: Optical Basicity: Theory and Application.

Dyon, Joël

Designer and Project Manager
Institut de Physique du Globe de Paris
1 rue Jussieu, 75005 Paris, France.

Favaro, Nicola

Laboratory Director, Stazione Sperimentale del Vetro
Via Briati 10, 30141 Venice, Italy
– 9.9: Glass Cullet: Sources Uses, and Environmental Benefits.

Fokin, Vladimir M.

Senior Research Fellow
Vavilov State Optical Institute
ul. Babushkina 36-1, 193 171 Saint Petersburg, Russia
– 5.4: Nucleation, Growth, and Crystallization in Inorganic Glasses.

Fotheringham, Ulrich

Senior Principal Scientist
Central Research and Technology Development
Schott AG, 55014 Mainz, Germany
– 3.7: Structural Shear, and Stress Relaxation in Glass-forming Liquids.

Freestone, Ian, C.

Professor, Institute of Archaeology,
University College London
31–34 Gordon Square, London WC1H 0PY, UK
– 10.3: Roman Glass.

Galoisy, Laurence

Maître de conférences, Institut de Mineralogie
de Physique des Matériaux et de Cosmochimie
Sorbonne Université, UMR CNRS 7590
Muséum National d'Histoire Naturelle, IRD
4 Place Jussieu, 75005 Paris, France
– 6.2: The Color of Glass.

Garden, Jean-Luc

R&D Engineer, CNRS, Institut Néel and Université de Grenoble
Alpes, F-38042 Grenoble, France
– 3.2: Thermodynamics of Glasses.

Gin, Stéphane

Research Director, CEA DEN/DTCD Marcoule
30207 Bagnols sur Cèze, France
– 9.11: Nuclear Waste Vitrification.

Girard, Sylvain

Professor, Laboratoire Hubert Curien, Univ Lyon
UJM Saint-Etienne, CNRS, IOGS, UMR 5516
18 rue du professeur Benoît Lauras
42000 Saint-Etienne, France
– 3.13: Radiation Effects in Glass.

Gonçalves, M. Clara

Professora auxiliar, Departamento de Engenharia Química, CQE,
Instituto Superior Técnico
Universidade de Lisboa
Av. Rovisco Pais 1049-001 Lisboa, Portugal
– 8.2: Sol-gel Processes and Products.

Gouillart, Emmanuelle

Director, CNRS-Saint-Gobain Laboratory of Glass Surface and
Interfaces, Saint-Gobain Research Paris
39 quai Lucien Lefranc, 93303 Aubervilliers cedex, France
– 4.4: Chemical Diffusion in Multicomponent Glass-forming Systems.

Greaves, Neville G. (deceased)

Distinguished Research Fellow
Department of Materials Science and Metallurgy
University of Cambridge, Cambridge CB3 0FS, UK
– 2.5: The Extended Structure of Glass.

Guadagnino, Emanuel

European Pharmacopeia Expert, Italian Delegate
via Paolo Erizzo 20, Venezia (Ve) 30126, Italy
– 7.7: Glass for Pharmaceutical Use.

Guillou, Hervé

Maître de conférences, CNRS
Institut Néel and Université de Grenoble Alpes
38042 Grenoble, France
– 3.2: Thermodynamics of Glasses.

Gujrati, Purushottam D.

Professor, Department of Physics
Department of Polymer Science
The University of Akron, Akron
OH 44325, USA
– 3.3: The Glass Transition and the Entropy Crisis.

Gupta, Prabhat K.

Emeritus Professor, Department of Materials
Science and Engineering
The Ohio State University, Columbus OH 43235, USA
– 2.7: Topological Constraint Theory of Inorganic Glasses.

Gy, René

Department Manager, Thermomechanics & Modelling
Saint-Gobain Research Paris, 39 Quai Lucien Lefranc
93302 Aubervilliers, France
– 9.2: Tempered and Laminated Glazing for Cars.

Haas, Karl-Heinz

Research Scientist, Fraunhofer-Institut für Silicatforschung,
Neunerplatz 2, D-97082 Würzburg
Germany
– 8.9: Hybrid Inorganic–Organic Polymers.

Habasaki, Junko

Assistant Professor, School of Materials and Chemical Technology,
Tokyo Institute of Technology
4259 Nagatsuta-cho, Yokohama, Kanagawa 226-8502
Japan
– 4.6: Atomistic Simulations of Transport Properties.

Hampshire, Stuart

Emeritus Professor of Materials Science
Materials and Surface Science Institute
University of Limerick, Limerick V94 T19PX, Ireland
– 7.8: Oxynitride Glasses.

Hand, Russell J.

Professor of Glass Science & Engineering
Department of Materials Science & Engineering
University of Sheffield, Sir Robert Hadfield Building
Mappin Street, Sheffield S1 3JD, UK
– 3.11: Mechanical Properties of Inorganic Glasses.

Hannon, Alex C.

Research Scientist, ISIS Facility
R3, Rutherford Appleton Laboratory
Chilton, Didcot, Oxon OX11 0QX, UK
– 2.1: Basic Concepts of Network Glass Structure.

Haus, Reiner

Managing Director, Dorfner Analysenzentrum und
Anlagenplanungsgesellschaft mbH (ANZAPLAN), Scharhof 1,
92242 Hirschau, Germany
– 5.1: Chemical Analyses and Characterization of Glass.

Hayashi, Akitoshi

Professor, Department of Applied Chemistry
Faculty of Engineering, Osaka Prefecture University
1-1 Gakuen-cho, Naka-ku, Sakai
Osaka 599-8531, Japan
– 9.5: Sulfide Glass Electrolytes for All-solid-state Batteries.

Hehlen, Bernard

Professor, Laboratoire Charles Coulomb, UMR 5221 CNRS,
Université de Montpellier, 34095 Montpellier, France
– 3.4: Atomic Vibrations in Glasses.

Hellmann, Roland

Senior Scientist, ISTerre- Geochemistry Group
CNRS, Université Grenoble Alpes
38058 Grenoble Cedex 9, France
– 5.12: Mechanisms of Glass Corrosion by Aqueous Solutions;
7.3: Corrosion of Natural Glasses in Seawater.

Helsch, Gundula

Senior Scientist, Institute of Non-Metallic Materials, Clausthal
University of Technology
Zehnterstraße 2a, 38678 Clausthal-Zellerfeld, Germany
– 9.4: Glass for Solar-energy Technologies.

Henderson, Grant S.

Professor, Department of Earth Sciences,
University of Toronto
22 Russell St., Toronto, Ontario M5S 3B1, Canada
– 2.2: Structural Probes of Glass.

Heo, Jong

Professor, Department of Materials Science and Engineering
Pohang University of Science and Technology (POSTECH),
Gyeongbuk 790784,
Republic of Korea
– 6.6: Optoelectronics: Active Chalcogenide Glasses.

Hess, Kai-Uwe

Academic Staff, Department for Earth and Environmental Science,
Ludwig-Maximilians Universität München, Theresienstr. 41/III,
80333 Munich, Germany
– 7.2: Geological Glasses.

Heuss-Aßbichler, Soraya

Professor, Section of Mineralogy
Petrology and Geochemistry
Department for Earth and Environmental Science
Ludwig-Maximilians Universität München
Theresienstr. 41/III, 80333 Munich, Germany
– 9.10: Immobilization of Municipal and Industrial Waste.

Höche, Thomas

Head of the Optical Materials and Technologies Department,
Fraunhofer Institute for Microstructure of Materials and Systems
IMWS
Walter-Huelse-Strasse 1, D-06120 Halle (Saale), Germany
– 2.3: Microstructure Analysis of Glasses and Glass Ceramics.

Hofmeister, Anne

Research Professor, Department of Earth and Planetary Sciences
Washington University, St. Louis, MO 63130, USA
– 4.5: Thermal Diffusivity and Conductivity of Glasses and Melts.

Höland, Wolfram

Former Head of Fundamental Research on Glass and Ceramics,
Ivoclar Vivadent AG, R&D, Bendererstr. 2, 9494 Schaan,
Principality of Liechtenstein
– 8.5: Dental Glass Ceramics.

Inoue, Akihisa

Professor, International Institute of Green Materials, Josai
International University, Togane 283-8555, Japan; School of
Materials Science and Engineering
Tianjin University, Tianjin 300072, China;
Department of Physics, King Abdulaziz University, Jeddah 22254,
Saudi Arabia; National University of Science and Technology
(MISIS), Leninsky prosp. 4
Moscow 119049, Russia
– 7.10: Bulk Metallic Glasses.

Ispas, Simona

Maître de conférences, Laboratoire Charles Coulomb
Université de Montpellier, CNRS, 34095
Montpellier France
– 2.9: First-principles Simulations of Glass Formers.

Ivanovskaya, Irina, S.

Former Senior Researcher, Chemistry Institute c/o Saint Petersburg
State University Physical Chemistry Department, Saint Petersburg
State University
Universitetskii prospect, 26, Petrodvorets
198504 Saint Petersburg, Russia
– 5.8: The Glass Electrode and Electrode Properties of Glasses.

Jatzwauk, Christoph

Managing Director F.I.C. Germany GmbH
Eichenstraße 51, 92637 Weiden, Germany
– 9.7: Design and Operation of Glass Furnaces.

Jones, Julian R.

Professor of Biomaterials, Department of Materials, Imperial
College London, Exhibition Road, London SW7 2AZ, UK
– 8.4: Bioactive Glasses.

Kamihori, Toru

Deputy General Manager, Director, Glass Process Division, AGC
Inc., Innovative Technology Laboratories
Technology General Division, 1-1 Suehiro-cho
Tsurumi-ku, Yokohama-shi Kanagawa 230-0045, Japan
– 1.4: Primary Fabrication of Flat Glass.

Karlsson, K. Stefan R.

Senior Scientist, RISE Glass (Former Glafo)
Division of Built Environment, RISE Research Institutes of Sweden,
SE-351 96 Växjö, Sweden
– 3.12: Strengthening of Oxide Glasses.

Kob, Walter

Professor, Laboratoire Charles Coulomb, Université de Montpellier
CNRS, 34095 Montpellier, France
– 2.9: First-principles Simulations of Glass Formers.

Koebel, Mathias M.

Head, Laboratory for Building Energy Materials and Components,
EMPA, Überlandstrasse 129
8600 Dübendorf, Switzerland
– 8.3: Silica Aerogels.

Ladirat, Christian

Deputy Manager of Waste Containment and Vitrification Service,
Commissariat à l'Énergie Atomique
DEN/DTCD Marcoule, 30207 Bagnols sur Cèze, France
– 9.11: Nuclear Waste Vitrification.

Lehuédé, Patrice

Free Researcher, Centre de Recherche et Restauration des Musées
de France, 14, quai François Mitterrand
75001 Paris, France
– 5.11: Durability of Commercial-type Glasses.

Li, Hong

Senior Scientist, Nippon Electric Glass US, Fiber Glass Science &
Technology, PPG Industries, 940 Washburn Switch Rd., Shelby, NC
28150-9089, USA
– 1.6: Continuous Glass Fibers for Reinforcement.

Libourel, Guy

Professor, Université Côte d'Azur, Observatoire de la Côte d'Azur
CNRS, UMR 7293 Lagrange, Boulevard de l'Observatoire
CS34229, 06304 Nice Cedex 4, France
– 7.1: Extraterrestrial Glasses.

Livage, Jacques

Emeritus Professor, Collège de France and French Academy of
Sciences
Laboratoire de Chimie de la Matière Condensée de
Paris CNRS, UMR-7574, 4 place Jussieu, 75252 Paris Cedex 05
France
– 8.1: Biogenic Silica Glasses.

Lopez, Pascal Jean

Research Director and Director of the Observatoire Hommes-
Milieux Port Caraïbe, Biologie des Organismes Aquatiques et
Écosystèmes (BOREA), UMR CNRS 7208
Muséum National d'Histoire Naturelle, Sorbonne Université; IRD-
207 Université Caen Normandie; and Université des Antilles, 75005
Paris, France
– 8.1: Biogenic Silica Glasses.

Louter, Christian

Professor of Building Construction
Institute of Building Construction
Faculty of Civil Engineering
Technische Universität Dresden
01062 Dresden, Germany
– 9.1: Structural Glass in Architecture.

Louzguine-Luzgin, Dmitri V.

Professor, Principal Investigator, Laboratory Director, WPI
Advanced Institute for Materials Research and AIST-Tohoku
Mathematics for Advanced Materials – Open Innovation
Laboratory, Tohoku University
Aoba-Ku, Sendai 980-8577, Japan
– 7.10: Bulk Metallic Glasses.

Lucas, Jacques

Emeritus Professor, French Academy of Sciences, Université de
Rennes I
Verres et Céramiques, Institut des Sciences Chimiques
UMR-CNRS 6226, 35700 Rennes, France
– 6.5: Fluoride and Chalcogenide Glasses for Mid-infrared Optics.

Machon, Denis

Maître de conférences, Institut Lumière Matière
Université Claude Bernard Lyon 1, 10 rue Ada Byron
69622 Villeurbanne Cedex, France
– 3.10: Pressure-Induced Amorphization.

McMillan, Paul F.

Sir William Ramsay Professor of Chemistry
Christopher Ingold Laboratory, Department of Chemistry,
University College London, 20 Gordon Street
London WC1H 0AJ, UK
– 3.9: Polyamorphism and Liquid-Liquid Phase Transitions; 3.10:
Pressure-Induced Amorphization.

Maeda, Kei

Fellow, Asahi Glass Company Inc.
Research Center, 1150 Hazawa-cho, Kanagawaku
Yokohama 221-8755, Japan
– 6.10: Screens and Displays.

Malfait, Wim J.

Group Leader Superinsulation Materials, Laboratory for Building
Energy Materials and Components, EMPA
Überlandstrasse 129, 8600 Dübendorf, Switzerland
– 8.3: Silica Aerogels.

Martlew, David (deceased)

Glass Technologist, 15 Cecil Drive, Eccleston,
St Helens, UK
– 10.8: Stained Glass Windows.

Mills, Kenneth C. (deceased)

Former Professor, Department of Materials
Imperial College, London SW7 2AZ, England, UK
– 7.4: Metallurgical Slags.

Montigaud, Hervé

R&D Engineer, Associate Researcher
Surface du Verre et Interfaces
Saint-Gobain Research Paris, UMR 125 CNRS
39 Quai Lucien Lefranc, 93303 Aubervilliers Cedex, France
– 5.11: Durability of Commercial-type Glasses.

Muijsenberg, Erik

Vice-president, Glass Service a.s
Rokytnice 60, 75501 Vsetin, Czech Republic
– 9.8: Physics and Modeling of Glass Furnaces.

Mysen, Bjorn

Senior Staff Member, Geophysical Laboratory
Carnegie Institution for Science, 5251 Broad Branch Rd
Washington, DC 20015, USA
– 2.6: Structure of Chemically Complex Silicate Systems; 5.5:
Solubility of Volatiles.

Ni, Huaiwei

Professor of Geochemistry, CAS Key Laboratory of Crust-Mantle
Materials and Environments School of Earth and Space Sciences,
University of Science and Technology of China, Hefei 230026,
China
– 4.3: Diffusion in Oxide Glass-forming Systems.

Ojovan, Michael I.

Professor, Department of Materials, Imperial College London
London SW7 2AZ, UK
– 3.1: Glass Formation.

Oktik, Sener

Chief Technology Officer, Türkiye Şişe ve Cam Fabrikaları A.Ş.,
Science and Technology Center
Cumhuriyet Mah. Şişecam Yolu Sok. No:2 41400 Gebze-Kocaeli,
Turkey
– 6.7: Modification Technologies of Glass Surfaces; 6.8: Thin-Film
Technologies for Glass Surfaces.

Ollier, Nadège

Research Scientist, Laboratoire des Solides Irradiés
Ecole polytechnique, CNRS, CEA, 91128 Palaiseau Cedex, France
– 3.13: Radiation Effects in Glass.

Ottonello, Giulio

Former Chair of Geochemistry, Laboratorio di Geochimica at
DISTAV, University of Genoa
Corso Europa 26: 16132 Genova, Italy
– 5.3: Thermodynamic Models of Oxide Melts.

Panteix, Pierre-Jean

Research Engineer, CNRS, Institut Jean Lamour UMR 7198;
Campus ARTEM, 2 allée André Guinier
BP 50840, 54011 Nancy Cedex, France
– 5.10: Glass/Metal Interactions.

Parker, John M.

MA (Cantab), FSGT, FIMMM, CEng
Professor Emeritus
Department of Materials Science and Engineering
Sheffield University
Sir Robert Hadfield Building, Mappin Street
Sheffield S10 5TX, UK
– 9.12: The International Commission on Glass (ICG); 10.8: Stained
Glass Windows.

Parsons, Andrew James

Senior Research Fellow, Faculty of Engineering
University of Nottingham, University Park
Nottingham NG7 2RD, UK
– 7.9: Phosphate Glasses.

Patzig, Christian

Senior Research Scientist, Fraunhofer Institute for Microstructure
of Materials and Systems IMWS
Walter-Huelse-Strasse 1, D-06120 Halle (Saale), Germany
– 2.3: Microstructure Analysis of Glasses and Glass Ceramics.

Petitjean, Carine

Maître de conférences, Université de Lorraine
Institut Jean Lamour UMR 7198, Campus ARTEM, 2 Allée André
Guinier, BP 50840, 54011 Nancy Cedex, France
– 5.10: Glass/Metal Interactions.

Peuget, Sylvain

Senior Research Scientist, Commissariat à l'Énergie Atomique,
Nuclear Energy Division, BP 17171, 30207 Bagnols-sur-Cèze Cedex,
France
– 3.13: Radiation Effects in Glass.

Pinet, Olivier

Head of Research Laboratory for the Development of Conditioning
Matrices, Commissariat à l'Énergie Atomique, DEN/DTCD
Marcoule, 30207 Bagnols sur Cèze, France
– 9.11: Nuclear Waste Vitrification.

Podor, Renaud

Research Engineer CNRS, Institut de Chimie Séparative de
Marcoule, UMR 5257; Bât. 426, BP 17171, 30207 Bagnols sur Cèze
Cédex, France
– 5.10: Glass/Metal Interactions.

Pomeroy, Michael J.

Professor, Materials Science and Technology, Materials and Surface
Science Institute, University of Limerick Limerick V94 T19PX,
Ireland
– 7.7: Oxynitride Glasses.

Prescott, Patrick J.

Senior Engineer, Owens Corning Science & Technology Center,
Granville, OH 43023, USA
– 1.7: Simulation in Glass Processes.

Prinz, Sebastian

Business Development Director, Dorfner Analysenzentrum und
Anlagenplanungsgesellschaft mbH (ANZAPLAN), Scharhof 1,
92242 Hirschau, Germany
– 5.1: Chemical Analyses and Characterization of Glass.

Purnode, Bruno

Senior Research Associate
Owens Corning Science & Technology Center
Granville, OH 43023, USA
– 1.7: Simulation in Glass Processes.

Rapin, Christophe

Professor, Université de Lorraine
Institut Jean Lamour UMR 7198
Campus ARTEM, 2 Allée André Guinier, BP 50840
54011 Nancy Cedex, France
– 5.10: Glass/Metal Interactions.

Richet, Pascal

Senior Physicist, Institut de Physique du Globe de Paris
1 rue Jussieu, 75005 Paris, France
– Preface; General and Section Introductions; 3.6: Thermodynamic
Properties of Oxide Glasses and Liquids; 10.9: Furnaces and
Glassmaking Processes: from Ancient Tradition to Modernity;
10.10: Glass, the Wonder Maker of Science; 10.11: A History of
Glass Science; Indexes.

Roggendorf, Hans

Professor, Nonmetallic-inorganic Materials, Martin-Luther-
Universität Halle-Wittenberg, Institute of Physics
D-06099 Halle (Saale), Von-Danckelmann-Platz 3
Germany
– 7.5: Water Glass.

Roos, Christian

Professor, Department of Mineral Engineering, RWTH Aachen
Nizzaallee 75, Aachen, Germany
– 1.5: Fabrication of Glass Containers.

Roskosz, Mathieu

Professor, Cosmochimie, IMPMC, CNRS UMR 7590, Muséum
National d'Histoire Naturelle, 57 rue Cuvier, 75231 Paris Cedex 05,
France
– 4.4: Chemical Diffusion in Multicomponent Glass-forming
Systems.

Rössler, Ernst A.

Emeritus Professor, Experimentalphysik II
Universität Bayreuth, 95441 Bayreuth, Germany
– 8.6: Relaxation Processes in Molecular Liquids.

Ruffle, Benoît

Professor, Laboratoire Charles Coulomb, UMR 5221 CNRS
Université de Montpellier, 34095 Montpellier, France
– 3.4: Atomic Vibrations in Glasses.

Rüssel, Christian

Professor, Otto-Schott-Institut, Jena University
Fraunhoferstr. 6, 07743 Jena, Germany
– 5.9: Electrochemistry of Oxide Melts.

Savaëte, Bernard

Founder and President, BJS.Différences
33 Rue Jules Ferry, 92400 Courbevoie, France
– 9.6: The World of the Flat-glass Industry: Key Milestones, Current Status and Future Trends.

Schmelzer, Jörn W.P.

Leading Research Scientist (retired), Institut für Physik
Universität Rostock, Wismarsche Str. 43-45
18057 Rostock, Germany
– 5.4: Nucleation Growth, and Crystallization in Inorganic Glasses.

Schmucker, Éric

Research Scientist, Commissariat à l'Énergie Atomique, Université
Paris-Saclay, 91191 Gif-sur-Yvette, France
– 5.10: Glass/Metal Interactions.

Schottner, Gerhard

Research Scientist, Fraunhofer-Institut für Silicatiforschung,
Neunerplatz 2, D-97082 Würzburg
Germany
– 8.9: Hybrid Inorganic–Organic Polymers.

Schweiger, Marcel

Director, Inorganic Chemistry R&D, Ivoclar Vivadent AG, R&D,
Benderstr. 2, 9494 Schaan, Principality of Liechtenstein
– 8.5: Dental Glass Ceramics.

Shortland, Andrew J.

FSA FGS, Professor of Archaeological Science, Director
Cranfield Forensic Institute, Director of Research
Cranfield Defence and Security
Cranfield University
Wilts SN6 8LA, UK
– 10.2: Ancient Glass Late Bronze Age.

Sökmen, İlkey

Surface Technologies Manager, Türkiye Şişe ve Cam Fabrikaları A.
Ş., Science and Technology Center
Cumhuriyet Mah. Şişecam Yolu Sok. No:2 41400 Gebze-Kocaeli,
Turkey
– 6.7: Modification Technologies of Glass Surfaces; 6.8: Thin-Film Technologies for Glass Surfaces.

Solvang, Mette

Chief Engineer, Group Research & Development
Rockwool International A/S, 2640 Hedehusene
Denmark
– 9.3: Stone and Glass Wool.

Souquet, Jean-Louis

Emeritus Professor, Laboratoire d'électrochimie et de
physicochimie des matériaux et des interfaces
PHELMA, BP 75, 38402 Saint Martin d'Hères Cedex
France
– 4.2: Ionic and Electronic Transport.

Stebbins, Jonathan F.

Professor, Department of Geological Sciences
Stanford University, Stanford, CA 94305-2115, USA
– 2.4: Short-range Structure and Order in Oxide Glasses.

Stern, E. Marianne

Independent Researcher, Nieuwe Passeerdersstr. 186
1016XP Amsterdam, The Netherlands
– 10.5: Ancient Glassworking.

Takada, Akira

Visiting Professor, University College London
Gower Street, London W1E 6BT, UK, and Ehime University, 10-13
Dogo-Himata
Matsuyama, Ehime 790-8577
Japan. Former Junior Fellow
Research Center, AGC Inc., 1150 Hazawa-cho
Yokohama 221-8755, Japan
– General Introduction; 2.8: Atomistic Simulations of Glass Structure and Properties.

Tatsumisago, Masahiro

Professor, Department of Applied Chemistry, Faculty of
Engineering, Osaka Prefecture University

Preface

When art meets glassmaking: the visit of the Duchess of Berry (1798–1870) in 1824 to the plate-glass factory of the Royal Manufacture of Saint-Gobain as depicted by Édouard Pingret (1788–1869). The stifling heat, the noise of the furnaces, and the danger for the workers of the molten glass poured from the pot and spread with the steel roller on the large table (Chapter 10.9) have all vanished. Only the theatrical aspect of the scene remains, highlighted by the tall curtain, the duchess's light-colored dress echoing the worker's white smocks, and the children watching the show from the balcony. *Source:* Photo courtesy Saint-Gobain Archives.

The *Encyclopedia* has been designed to satisfy the needs and curiosity of a broad audience interested in the nature, properties, fabrication, and history of glass and looking for consistent, comprehensive, and up-to-date information in a single book. More than 100 chapters involving even more glass experts have been written in a perspective that combines the various aspects of this unique material, be they scientific, technological, industrial, historical, or cultural. Whether coming from academia or industry, the authors have in common a long practice of glass. Their goal is to be informative without being pedantic, to be concrete without being boring, and to give a balanced overview of the field – in a word, to allow a large readership to understand both the amazing properties of the vitreous state and its peculiarities compared with those of other states of matter. Excluding the so-called spin glasses and other kinds of disordered physical systems, the *Encyclopedia* restricts itself to what is now termed *structural* glass.

In all chapters, the authors discuss glass from a materials-science standpoint, but their purpose is not to review in any detail the latest advances of interest to specialists only. Rather, in the form of scholarly introductions, it is to present every topic at a uniform level and in a self-consistent manner. In this way, the main points will be grasped and key information of fundamental or practical use will be made available. The neophyte reader will then be able to consult the specialized literature and, in particular, the select bibliography appended to each chapter.

This approach does not imply that only elementary features are presented, but that concepts are appropriately introduced and any technical information clearly explained so as to avoid the common defect underlined in 1911 by the astronomer Percival Lowell (1855–1916) who emphasized in *Mars and its Canals* that “nothing in any branch of science is so little known as its articulation, — how the skeleton of it is put together, and what may be the mode of attachment of its muscles.” Whereas a very few chapters give a flavor of current technicalities involved in glass research, newly investigated topics are also considered with the goal of ensuring that the *Encyclopedia* remains a useful reference over an extended period of time. Although those views that are at this moment very speculative are generally not discussed at length, they may be stated in the final *Perspectives* of the chapters.

Given the diversity of topics treated, the name of *Encyclopedia* (*Kuklos paideia*, cycle of enlightenments, in Greek) is particularly appropriate. The surprising fact is that such a reference work was not existing at all for glass, in general, even though more than hundreds of thousands of encyclopedias have now been devoted to any topic worth of attention, including glass art in particular. The

Encyclopedia consists of 10 sections preceded by a general introduction and concluded by a postface. It begins with glassmaking and continues with structural, physical, and chemical properties. The stage is then set to turn to issues pertaining to light, to the main inorganic glass families, to organically related glasses, to environmental and other industrial issues, and, finally, to the main facets of the rich glass history. Even in more than 100 chapters, it has not been possible to deal with every important topic relevant to glass. A few more chapters would have been welcomed, but their advantages would not have outweighed the inconvenience of a longer publication time, especially for the *Encyclopedia* contributors.

Each section is preceded by a short introduction summarizing in a few sentences the contents of its chapters for helping readers to decide which ones fit their own interest best. Another purpose of these introductions is to show that, from the first to the last, the chapters are telling a consistent story. Although efforts have been made to avoid overlap, some limited duplication was inevitable to make sure that most contributions could be read independently of the others. Of course, boundaries between chapters or sections are not always clear-cut, so that some arbitrariness has been involved in their delineation. And whereas the scientific and technology contents of the chapters will probably speak for themselves, it might be useful to note that historical aspects are dealt with not only in the last section but also elsewhere each time they can help to open deeper perspectives. As for the *Culture* included in the title of the *Encyclopedia*, it is explicitly treated only in the very last chapter but pervades a great many others, for example, in the history section where beautiful pieces of art are in particular reproduced.

At the end of this endeavor, it is now a pleasure to acknowledge (i) the encouragement initially provided by R. Conradt, N.G. Greaves, J. Livage, J. Lucas, B. Mysen, A. Takada, and Y. Yue when the project took shape; (ii) the warm welcome this project received through G. Geiger and A. Lekhwani when submitted to the American Ceramic Society and John Wiley & Sons; (iii) the invaluable help then brought all the way by Reinhard Conradt and Akira Takada through their constant advice, support, friendship, and careful reviewing work; (iv) the great many graphics and pictures neatly prepared by Joël Dyon to highlight the matter presented in numerous chapters; (v) the efforts of 151 authors working in 23 countries who participated in this ambitious endeavor and went responsively throughout an editorial process aimed at ensuring an overall homogeneity of style and content, and incorporated in their texts the relevant historical and cultural aspects evoked by the *Encyclopedia* title; (vi) the thoughtful comments and apt observations provided

by nearly 200 reviewers whose names are included at the beginning of every chapter to recognize publicly their contributions; (vii) the original pictures or help in different matters generously provided by colleagues, friends, and institutions whose names are mentioned at the relevant places; (viii) the Humboldt Stiftung, the Ludwig-Maximilians-Universität, and Donald Dingwell for the fruitful work done in Munich; (ix) the so many things about glass or high-temperature techniques and processes discussed over the years with T. Atake, J.-L. Bernard, Y. Bottinga, R. Conradt, K.-U. Hess, R. Kerner, B. Mysen, G. Ottonello, J.-P. Petitot, J. Roux, A. Sipp, J.F. Stebbins, A. Takada, C. Téqui, and other colleagues too numerous to be mentioned; (x) the Table of ion data compiled by J.F. Stebbins, the help provided at various stages of this study by É. Fareau, B. Gasparyan, K.-U. Hess, A. Hofmeister, K. Meliksetian, B. Mysen, and M. Wolf as well as thoughtful comments by J.M. Parker and R.F. Tournier on the section introductions; (xi) and finally Michael Leventhal who oversaw the project at Wiley, Stefanie Volk for copy editing and Viniprammia Premkumar for smooth and responsive production of the book.

The *Encyclopedia* is dedicated to them and to all people whose efforts throughout the ages made glass the astonishing, ubiquitous material it has become.

Section VII. Inorganic Glass Families

Figure 1 The oldest known glass phases, dating back to the beginnings of the solar system: the 4.57-billion-year-old matrix (dark black) of *chondrite* meteorites, which owe their names to their spherical *chondrules*. Shown here is a big one of 3 mm in size made up of a highly birefringent, rapidly quenched olivine crystal [(Fe,Mg)SiO₄]. Thin section of Chainpur chondrite, which fell in 1907 in India. Optical micrograph under polarized light by Maxime Bronchy, courtesy François Robert, MNHN, Paris.

Inorganic glasses are as old as the first planetary bodies, which probably began to form by accretion of celestial dust very long before the birth of the solar system 4.57 billion years ago. As indicated by the amorphous *mesostasis* of certain meteorites (Figure 1), this was the time when the oldest known glasses were quenched from the high-temperature accretion conditions prevailing in *protoplanets*. Extraterrestrial glasses have then variously resulted from volcanic planetary activity, the effects of high-pressure impacts, and irradiation or friction upon entry of cometary or asteroidal material into the Earth's upper atmosphere. These processes are described in the first chapter of this section by G. Libourel who also explains how important information on the early history of the solar system can be derived from studies of these different kinds of glasses (Chapter 7.1).

On Earth, too, glasses formed very early. In contrast to the almost infinite metastability enjoyed under high vacuum by their extraterrestrial counterparts, they suffer more or less rapidly from weathering by aqueous solutions. They exhibit widely differing compositions, which translate into very large viscosity increases at magmatic temperatures from SiO_2 -poor to SiO_2 -rich lavas; eruptive styles vary accordingly from gentle to violently explosive and in productions ranging from aerodynamically drawn glass fibers to massive obsidian blocks. These effects are discussed by C. De Campos and K. Hess in the chapter devoted to natural glasses, which also deals with fulgurites, formed by lightning, as well as tektites and silica Libyan Desert glass whose formation is induced by the fall of cometary or meteorite impacts (Chapter 7.2). Because most fresh lavas erupt on Earth along the extensive mid-ocean ridges, very large amounts of glass form upon quenching by seawater under conditions that are, therefore, prone to rapid corrosion. As described by R. Hellmann, the mechanisms of both biotic and abiotic processes at work have been largely deciphered and appear to play a considerable role in the global geochemical cycles of chemical elements (Chapter 7.3).

The rest of this section is devoted to man-made glasses. In metallurgy, 400 million tons of Ca-rich slags yearly produced are closely related to natural glasses because they originate in the melting of ores in blast furnaces where metal oxides are reduced by reaction with coke. Owing to their low SiO_2 contents, slags are very fluid and have a high electrical conductivity. These properties reviewed by K.C. Mills play a critical part in the kinetics of metal processing; as a result of a strong chemical affinity for impurities, slags in addition concentrate sulfur and phosphorus, which would have deleterious effects on metal properties (Chapter 7.4). The so-called water glasses are also SiO_2 poor but alkali rich and are named after their high solubilities in aqueous solutions. These features discussed by H. Roggendorf make them valuable as highly reactive sources of silica and alkalis, or as precursors in silicate synthesis, in the form of monomeric or polymeric species in

concentrated aqueous solutions (Chapter 7.5). On the contrary, borosilicate glasses are extremely stable in aqueous solutions; in addition, they are easily melted and exhibit unusually low thermal expansion. As described by R.E. Youngman, these features result from the very low melting temperature of 712 K of B_2O_3 along with mixing of B^{3+} and Si^{4+} in the anionic framework made possible by association of boron with charge-compensating cations; the entropy of Si-B mixing thus enhances the depressing effects of B_2O_3 on liquidus temperatures without affecting the polymerization state and stability of the material (Chapter 7.6). Since a low reactivity with aqueous solutions and other liquids is a prerequisite in pharmacy, borosilicates are the prime glass containers in this domain although chemical processes such as ion exchange, silicization, or reaction with ammonium sulfide presented by D. Zuccato and E. Guadagnino can increase the hydrolytic resistance of usual container glass for less demanding applications (Chapter 7.7).

The next three chapters are devoted to not-so-well known families of glasses. First, oxynitrides owe their name to the large amounts of nitrogen that can be chemically dissolved in a rather wide range of silicate compositions; S. Hampshire and M. Pomeroy document why their network is rigidified when oxygens are substituted by cross-linking nitrogens and, thus, why they display improved mechanical properties (Chapter 7.8). With widely differing PO_4 chain structures, the phosphate glasses addressed by A. Parsons distinguish themselves by their ability to accommodate large concentrations of a great many modifier oxides, which has resulted in a variety of applications ranging from baking powder and *phosphors* to nuclear waste storage and high power lasers (Chapter 7.9). Although they were first produced as ribbons only in the 1960s, metallic glasses constitute a very rapidly developing family, which combines the traditional advantages of metals and glasses with regard to mechanical, magnetic, and molding properties. Owing to the poor vitrifiability of metals, the main difficulty encountered was to increase the size of the glass pieces obtained in the bulk. As explained by D. Louzguin-Luzgin and A. Inoue, the solution was to turn to multicomponent systems so as to take advantage of smaller intervals between liquidus and glass transition temperatures and make crystal nucleation and growth more difficult (Chapter 7.10).

The last chapter is devoted to partially crystallized glasses known as *glass ceramics* whose practical applications range from familiar cooktop panels to large telescope mirrors. The main features presented by M. Comte are thus the way in which their microstructure is engineered by appropriate choices of chemical composition, nucleating agents and heat treatments to grow, directly or after phase separation, and the desired crystalline phases that will confer outstanding chemical or thermal shock resistance to the resulting composite material, which may even be transparent (Chapter 7.11).

7.1

Extraterrestrial Glasses

Guy Libourel

Université Côte d'Azur, Observatoire de la Côte d'Azur, CNRS, Laboratoire Joseph-Louis Lagrange, Nice, France

1 Introduction

After four millennia of observations of the sky made with the naked eye, glass led Galileo (1564–1642) and his followers to discover a whole new celestial world through the lenses of their telescopes and to change accordingly man's worldview (cf. Chapter 10.10). To observe the universe still farther and in more detail, the need to increase the size of telescopes was clearly realized in the eighteenth century. Astronomy did not greatly benefit from the important advances made in the making of optical glass (Chapter 10.10); however, because reflecting telescopes (with metallic mirrors) then had the major advantage over refracting instruments of not been subject to chromatic aberration so that the only glass part was the eyepiece. In England, the German-born musician William Herschel (1738–1822) was at the forefront of these efforts not only as an observer and a theoretician but also as a mirror grinder and a telescope maker. Whereas about 100 nebulae were known when he began his observations, he described himself 2500 nebulae and star clusters in a series of papers devoted to the “Construction of the heavens” [1]. These observations of new worlds in the making quickly served as the basis of the theory propounded by Pierre-Simon de Laplace (1749–1827) to explain how all planets formed by condensation of interstellar dust and why they were orbiting in nearly the same plane and in the same direction in the Solar System [2].

But the chemical composition of the dust and the processes that formed planets orbiting around a star of course had to be determined. In this respect, a fundamental observation also made at the beginning of the

nineteenth century was that meteorites were fragments of heavenly bodies. That these objects were either stony or metallic (or both for a few of them), was especially striking as the Earth itself was later thought of consisting of a metallic core surrounded by a large silicate envelope. The relevance of meteorites to planetary studies was soon ascertained by the idea that these objects were fragmented remnants of planetesimals, the stable bodies larger than about 1 km resulting from the early accretion of dust, ice, and rocks in the protoplanetary disk. More recently, other kinds of extraterrestrial materials have been recovered. Millimeter-sized micrometeorites and interplanetary dust particles have been collected from the Earth's stratosphere to oceanic sediments whereas other samples have been brought back by space missions sent to the Moon (Apollo and Luna), a near-Earth asteroid named (25143) Itokawa (Hayabusa), a comet dubbed 81P/Wild (Stardust), and through the solar wind (Genesis).

Of particular interest is the glass phases found in these materials because they reveal the existence of melting stages in the planetary formation or activity and can even yield information on their kinetics. In contrast to most of their Earth counterparts, however, extraterrestrial glasses have generally encountered very peculiar and sometimes highly disequilibrium conditions, for instance, microgravity and high vacuum, high-velocity impacts, solar-wind irradiation, or extremely reduced environments caused by elevated carbon/oxygen ratios within the solar nebula. These extraterrestrial materials are thus of key importance not so much for inventorying the celestial bodies constituting the Solar System, but rather for understanding its formation and evolution since its birth.

Here, three different kinds of extraterrestrial matter will be described to illustrate the kind of conclusions that can be drawn from their studies. First, *chondrites*, the most primitive type of meteorites, show how

Reviewers: C. Engrand, Centre de Spectrométrie Nucléaire et de Spectrométrie de Masse, CNRS-Université Paris Sud, Orsay, France
R. Hewins, Earth and Planetary Sciences, Rutgers University, Piscataway, NJ, USA

extraterrestrial glass allows one to see far back in time for understanding the composition and evolution of the disk in terms of events, such as condensation of hot gases or transient heating caused by the formation of the Sun, whose mechanisms and timing must be determined [3]. Second, lunar glasses demonstrate the existence of two quite different glassmaking processes, the first extinct in the form of volcanic eruptions and the second still active through micrometeorite bombardment. Finally, small glass spherules found in special environments reveal that the Earth's surface is also continuously sprinkled by micrometeorites that reach the ground into a more or less preserved condition. A few implications of these results for cosmochemistry and glass science will finally be described.

2 Chondrules: The Oldest Glasses of the Solar System

Chondrites are stones representing about 85% of known meteorites. They are the oldest objects known to man because they formed right at the same time as the Solar System (Figure 1). They owe their name to their *chondrules* (*khondros*, small grain in Greek), the small spherical glass-rich inclusions that give them unique textures. In addition to chondrules, chondrites contain 10–15 vol % of refractory calcium–aluminum-rich inclusions (CAI), which were the first solids to condense at close heliocentric distances of 0.1 astronomical unit (1 AU $\approx$ 1.5 10^8 km, the mean Earth–Sun distance) out of a hot gaseous nebula [4]. As dated from the decay of ^{235}U (half-life of $0.71 \cdot 10^9$ years) and ^{238}U ($4.56 \cdot 10^9$ years), these

inclusions condensed 4567.30 ± 0.16 million years (My) ago [5], which represents our current best estimate of the age of the whole Solar System. Chondrules have the same age or may be slightly younger by up to 2–3 My [5].

Depending on chemical and mineral compositions, these meteorites are generally split into three main types, namely ordinary, carbonaceous, and enstatite (MgSiO_3 pyroxene rich) chondrites. Constituting up to 80% of their volumes, chondrules [6] are submillimeter- to millimeter-sized spherules in which a glass matrix coexists with olivines $[(\text{Mg,Fe})\text{SiO}_4]$, pyroxenes $[(\text{Mg,Fe,Ca})_2\text{Si}_2\text{O}_6]$, Fe–Ni metal, and sulfides like troilite (FeS) or oldhamite $[(\text{Ca,Mg})\text{S}]$. In view of large variations in bulk chemical composition, they are classified further into FeO-rich, FeO-poor, and Al-rich chondrules. In most chondrite groups, FeO-poor chondrules (type I) are dominant; on the other hand, Fe^{3+} -bearing chondrules (type II) are abundant only in ordinary chondrites, whereas Al-rich ones are scarce in all.

The glassy matrices display concomitantly large compositional variations (Table 1) since the SiO_2 content ranges from 40 to 85 wt % with a negative correlation with Al_2O_3 , CaO , and TiO_2 contents [7]. They display a wide variety of textures (Figure 2), some of which represent strong evidence for extremely rapid cooling from a molten or nearly completely molten state. In rare cases, they are entirely composed of glass, suggesting an even faster quenching. Other features that are clearly the result of very rapid cooling are dendritic and hopper-shaped crystals in a glassy matrix (Figure 2). But the most frequent texture is said to be *porphyritic*, meaning that some crystals are much larger than others, either olivines or pyroxenes, or both. Owing to the kinetics of crystal growth (Chapter 5.4), these chondrules likely cooled more slowly than those with radial or barred textures although they still may have solidified in a matter of hours.

From these observations and experimental work aiming at reproducing textures [10], it has been concluded that chondrules were produced by brief, incomplete melting (from about 1600 to 2000 K) of solid dust precursors in the solar protoplanetary disk (Figure 3). It also appears that chondrules solidified as melt droplets freely floating in space before being aggregated into the chondrite parent bodies [11]. The heat source that caused melting in the solar protoplanetary disk has not been unambiguously identified, however [5, 11]. The astrophysical or planetary origin of this source involved is still debated. Among possible processes are solar nebula lightning, nebular shocks driven by eccentric planetesimals, nebular shocks driven by disk-wide gravitational instabilities, or a sudden exposure to sunlight at distances smaller than 0.1 AU from the protosun, with subsequent launching in a magnetocentrifugal outflow (the so-called X-wind model).

Figure 1 Ferromagnesian chondrules and calcium, aluminum-rich inclusions cemented by a fine-grained matrix in the Allende CV3 carbonaceous chondrite. With more than 2 tons of fragments recovered, Allende is the biggest carbonaceous chondrite known so far. It fell on 8 February 1969 near Pueblito de Allende in Mexico.

Figure 3 Time-temperature pathway for the formation of chondrules and calcium, aluminum-rich inclusions from D. Hezel (pers. communication).

Experimental studies of chondrule melting and partial crystallization do allow chondrule formation models to be tested [12]. Specifically, chondrule textures are duplicated in dynamic crystallization experiments from peak temperatures from about 1600 to 2000 K at cooling rates ranging from 10^3 to 10 K/h [10]. These results strongly favor large-scale shocks driven by gravitational instabilities or possibly bow shocks driven by planetesimals on eccentric orbits [12]. Primordial dusty materials would have thus been flash-heated from less than 650 K to well above the liquidus (i.e. 1600–2000 K) and then cooled at elevated rates of the order of 10^4 – 10^3 K/h that would have slowed down to the 10^3 – 10 K/h range depending on the optical depth or dust/gas ratio of the medium. For a given chondrule, heating from the peak temperature and cooling down to the glass transition temperature (T_g) depending on the cooling rate would have lasted from hours to several tens of hours for the slowest cooling rates.

The nature of chondrule precursors is also a key question. Did chondrules form from condensate dust or liquid condensates from the nebula gas, from the recycling of previous generations of chondrules or chondrule-like materials, or from disrupted primordial planetesimals? [7, 10, 11]. As discussed since the early 1970s, another important problem is whether moderately volatile elements present such as Na or K have been lost by evaporation or gained by condensation from the gaseous environment during chondrule-forming events [7]. Central to this issue are gas compositions and dust densities in the surroundings of chondrules. How so much dust could have concentrated in at least some places in the solar nebula and how non-nebular gas much enriched in volatile and moderately volatile elements could have been produced? Clearly, more theoretical work is needed to answer such questions.

Whereas chondrules are ubiquitous in almost all chondrite groups, their formation thus remains an enigmatic process. Many melting mechanisms have been put forward over the last decades to explain their igneous textures. One idea is that shock waves sent in by spiral waves in an asymmetrical disk or generated by large planetesimals passing through the dust-rich region heated and melted the starting materials of the chondrules. Other alternatives, such as an impact on molten or partially molten planetesimals, would also work for chondrule formation but need to be investigated. Quoting Alexander and Ebel [11], one may still wonder whether it will be possible to solve the apparent contradictions between the petrologic, isotopic, thermodynamic, and astrophysical constraints on chondrule formation.

3 The Lunar Glass-Bead Factory

3.1 Volcanic Glasses

Herschel himself believed to have observed volcanic eruptions on the Moon [13]. Although he was clearly mistaken on this count, extinct lunar volcanism has been well documented by samples brought back by Space missions. According to radiometric dating, the Moon formed ~ 4.5 billion years ago, about 30–100 million years after the Solar System [14], likely from the matter ejected into an Earth-orbiting disk after a massive, off-center collision of the proto-Earth with a smaller planet [15, 16]. The Moon had a mass large enough to have gone through an Earth-like geochemical differentiation into a metallic core and silicate mantle and crust. Its surface geology is dominated by alternation of lunar plains (*mare*, seas), e.g. some vast solidified pools of ancient iron-rich basaltic lava mainly found on the near side, and lunar highlands on the far side consisting of rocks named anorthosites, i.e. plagioclase feldspar cumulates, which are interpreted as the precipitated remnants of a wide lunar magma ocean.

Highland terrains are on the average older (4 and 3.85 billion years) than the mare where the majority of basaltic eruptions occurred from 3.5 to 3 billion years ago. The other major geologic process that has been affecting the Moon's surface is impact cratering caused by asteroid and meteorite bombardment. Through impact repetition, the outermost crust of the Moon is highly comminuted in the form of a *regolith* (*rhēgos*, blanket, *lithos*, rock), a layer of fine-grained particles and impact debris. As may be expected, the regolith is thicker on older highlands (~ 10 m) than on younger mare (~ 5 m), but in both instances it remains slowly stirred and mixed by new impacts. Figuratively termed *impact gardening*, this process is largely due to micrometeorites, which, thanks to the lack of an atmosphere, can reach the ground and affect its first few millimeters.

Samples of the lunar regolith include breccia and rock fragments from the local bedrock. They are fine grained with a density of ~ 1.5 g/cm³ and a particle size of less than 60–80 μ m for about half of their mass. A variety of colorful volcanic glasses (Figure 4) have also been found in the form of green spherules at the Apollo 15 site and of orange and brown spherules, along with black beads at the Apollo 17 site [17]. The orange glasses owe their unusual hue to high TiO₂ contents of up to about 16 wt % (Chapter 6.2), whereas the beads are black because of the presence of many tiny ilmenite (FeTiO₃) crystals on the olivine blade margins. These features are typical of lava fountain eruptions, possibly several days or weeks long, during which liquid droplets vitrified upon quenching when falling from

Figure 4 Lunar colorful glass beads collected by the Apollo 15 and 17 missions. (a) Quenched fire-fountain droplets of erupting high-Ti mare basalt dated at 3.48 Ga: sample made mostly of orange, fractured, and partially devitrified glass sphere with a small admixture of mare basalt fragments. (b) Close-up of some spheres, showing one (center) with four long olivine blades that grew from lower right to upper left; the black margins (tiny ilmenite crystals) can be differentiated from the colorless olivine in the blades. (c) Green glass beads of 40–250 μm size in the lunar sample 15426 collected by the Apollo 15 mission. (d) Sketch of a hypothetical lunar volcanic vent and fire fountain producing the features seen in the glass beads [8].

the vent on the ground. Depending on faster or slower cooling rates, the droplets of high-Ti mare basalt produced either quenched glass or crystallized beads. More information has been derived from other analyses. First, the iron redox state in these glasses and beads was equilibrated with an oxygen fugacity 1–2 log units below that of the Fe–FeO_x equilibrium [18]. Second, that the beads are coated with ZnS and other volatile materials indicate that they originated from gas-rich source regions.

These findings were quite unexpected because such pyroclastic (*pueros*, fire, *klastos*, broken) material point to past explosive volcanic activity, which is in principle caused by exsolution of volatiles (mainly water) out of the magma (Chapter 7.2). In other words, these glasses point to the former presence of rather large amounts of

water in the Moon. Recent discoveries of trace amounts of water in these lunar volcanic glasses [19] have also led to reject the traditional view that the Moon was virtually free of water. Since these contents are similar to those found in magmas produced at mid-ocean ridges on Earth (≈ 200 –700 ppm H₂O), they imply that lunar magmas originated from a region bearing about the same amount of water as the current Earth's upper mantle. Like on Earth (Chapter 7.2), the magma had deep sources, rose to the surface, thanks to a density lower than those of the surrounding rocks, and, through volatile release and expansion, fragmented and followed ballistic trajectories upon high-velocity eruption at the vent.

This new view has important implications regarding the formation of the Moon and on the way in which

volatile elements could have been retained upon a highly energetic giant impact. As the mantles of the Moon and Earth have similar compositions, however, it remains to explain why lunar samples are more depleted in volatile elements than terrestrial mantle rocks if the Moon formed from an Earth-orbiting disk of vapor and melt produced by a giant impact. Explaining the Moon's volatile depletion has been a long-standing mystery, yet it is a key piece of evidence about how the Earth–Moon system formed. In terms of a combination of dynamical, thermal, and chemical models, volatile depletion in the Moon can in fact be explained as preferential accretion of volatile-rich melt in the inner part of the disk where the Earth formed, rather than in the growing Moon, through volatile condensation upon cooling of the initially hot melt

[20]. Such a scenario illustrates how the Moon and Earth could have acquired important composition differences even though they resulted from the same giant impact.

3.2 Impact-Produced Glasses

A quite distinct kind of amorphous phase is also found in the regolith in the form of interstitial, flow-banded glass bonding together the constituents of the so-called *agglutinates*, namely small mineral grains, glass particles, or remnants of former agglutinates [21]. Along with a size of a few tens of micrometers to a few millimeters (Figure 5), agglutinates have a heterogeneous composition resulting from the presence of individual regolith

Figure 5 (a) Petrographic thin section of Apollo 16 regolith breccia 60016 where a few glass spherules are evident (http://meteorites.wustl.edu/lunar/60016ms_l.jpg). (b) Photomicrograph of a thin section of a large agglutinate fragment from the Apollo 17 regolith (Source: Photo courtesy Brad Jolliff). (c) Lunar impact spherules showing a variety of shapes, colors, and sizes hosted in the breccia of the lunar regolith brought to Earth by the NWA 8010 meteorite (<http://rse.s.anu.edu.au/research/annrep/ar2008/prise/hui.jpg>); observations similar to those made on Apollo 16 samples. (d) Sketch of the lunar surface as exposed to solar wind and constantly pounded by micrometeorites. Agglutinates and impact glass spherules can be found within the lunar soil and in microbreccias. Source: Credit: Larry Taylor.

particles. Other original features are highly irregular shapes and the presence of trapped bubbles and nanometric metallic iron globules. Given their rather uniform distribution in the regolith, the source of heat producing the cementing glass has to be extremely extended. This source is in fact the heat produced when, depending on incident velocities of up to tens of km/s, micrometeorites impact the fine-grained regolith, which then warms enough to melt and form the glass cementing mineral and rock fragments whose relative motion can then give rise to flow features. Upon melting, the material can in addition release the solar-wind-implanted hydrogen and helium, causing the presence of gas bubbles in the glass. As for the nanometric metallic iron inclusions, their size of a few tens of nm and their very low Ni content indicate that they formed through melting or vapor deposition of other lunar material rather than being brought to the Moon by meteorites.

Micron- to centimeter-sized glass spherules may form as well when a real meteorite impacts the lunar regolith. During the event, the melt splashes are thrown away and solidify by radiative cooling before landing. Their peculiarity in this respect is that the lack of an atmosphere and a gravity six times smaller than on Earth result in flight distances ranging from several meters to hundreds of kilometers. As a matter of fact, a single gram of lunar soil can give rise to more than 100 of these glass spherules. In general, their composition, size, and the shape allow them to be readily distinguished from pyroclastic spherules (Figure 5).

4 Cosmic Spherules

On Earth, small glass spherules have also been found, but in the unlikely environments of deep-sea sediments, polar ice sheets and, more recently, polar snow (Figure 6), very far from any volcanic source. Along with these completely melted spherules are also found partially melted, bubble-bearing, or scoriaceous material as well as unmelted, fine-grained, crystalline micrometeorites (Figure 7). All these samples thus were originally micrometeorites, in general related to the most primitive classes of carbonaceous chondrites, which were more or less heated upon descent in the Earth's atmosphere. These micrometeorites dominate the amount of extraterrestrial material accreted by Earth with an estimated flux of $40\,000 \pm 20\,000$ ton per year [23]. With a maximum grain size of about $200\,\mu\text{m}$, the glassy spherules account for around half of this amount.

Everything else been equal, heating and consequently changes to textures and mineralogical and chemical compositions are less intense for smaller particles and lower

Figure 6 Stony cosmic spherules; largest about $300\,\mu\text{m}$ in diameter. Scanning electron microscope micrograph. *Source:* Credit: Graciela Matrajt, Cosmic dust web page.

entry angles and velocities in the atmosphere. But the initial velocity is not very high. When traveling in space, such small particles of matter absorb solar radiation and re-emit energy in such a way that their orbital momentum is slightly modified. As a result of this Poynting–Robertson effect, they travel in a spiral way toward the sun at speeds of only a few tens of km/s (Figure 8). If their pathway at altitudes of 80–120 km crosses the upper atmosphere, they are thus slowly decelerated to their free-fall velocity. This is why these interplanetary dust particles or micrometeorites have been collected not only in the stratosphere by NASA aircrafts, but also on the ground. And the reason why they represent an important source of unbiased information about the nature of asteroids and comets [24] is that, in contrast, the much rarer and bigger meteorites reach the ground only if they are carried away by adequate gravitational instabilities and if they are large and strong enough to survive atmospheric entry without fragmentation or destruction.

To take full cosmochemical advantage of these samples, however, it is useful to determine the conditions under which the texture and mineralogy of the micrometeorites were modified. Of course, the spherical shape of the glass spherules result from surface tension effects on a material completely melted above $1400\,^{\circ}\text{C}$, which is then quenched before reaching the ground. More interesting, the manner in which the textural and chemical diversity of spherules depend on oxygen fugacity – i.e. on the

Figure 7 Influence of the initial speed and angle of entry in the atmosphere on the degree of heating, and thus on the texture of micrometeorites. (a) Fine-grained unmelted. (b) Coarse-grained unmelted. (c) Scoriaceous. (d) Relict-grain bearing. (e) Porphyritic. (f) Fully melted glass spherule. Also included are the conditions of heating suffered by large micrometeorites (200–400 μm) during atmospheric entry deduced from their texture and mineralogy [22].

Figure 8 Meteoroids entry in the Earth's atmosphere. Most tiny particles burn up more than 70 km above the surface, producing ionized gas trails called meteors. Larger objects can reach altitudes of 10–30 km before fragmenting, giving rise to a meteorite shower on the ground when fragments survive the burst. Largest objects not significantly decelerated, hitting the surface and producing a hypervelocity impact crater. *Source:* Colorized and slightly modified version of a classic educational illustration by E. L. Krinov; Image Credit: LPI.

altitude in the atmosphere where they break down – the duration of the heating pulse, and evaporative loss upon entry have been determined experimentally (Figure 7 and Table 1). Specifically, peak temperatures and cooling rates increase from porphyritic, to barred-olivine, crypto-crystalline, and glass spherules, and then to Ca–Al–Ti-rich (CAT) spherules.

This heating sequence leads to increasing CaO, Al_2O_3 , TiO_2 , and MgO and decreasing FeO contents. These trends are consistent with the results of mathematical modeling and experimental simulations of heating and evaporation performed with chondritic and solar chemical compositions [25]. Despite rather severe entry conditions, most of the cosmic spherules thus broadly preserved the original chondritic compositions and provide a means of sampling meteoroid types not represented by presently collected meteorites.

Numerical simulations of the atmospheric flight of micrometeoroids have also been performed for ranges of initial diameters (10–1000 μm), initial entry velocities (11–72 km/s), and entry angles (0–90°) [23]. It appears that peak temperatures experienced by submillimeter micrometeoroids rarely exceed 1700 °C. The maximum temperature and mass loss rate generally occur at altitudes between 85 and 90 km within about 1 second of the heating peak (Figure 8). A melted particle typically was calculated to spend about 2 seconds above the liquidus. In spite of this short time, the mass loss was important since typical cosmic spherules were 1.5–2 times bigger before melting, about half of all survivors larger than 70 μm being melted. This result does not match well the observation that many unmelted particles of up to 200 μm in size have been recovered in the polar collections.

Other simulations of the atmospheric entry of micrometeorites have thus been made, but none of them has yet yielded more accurate results because of the great many parameters involved, among others the nature, speed, and size of the precursor, friction effects, or the pressure, temperature, or chemical composition of the atmosphere.

During the deceleration of the extraterrestrial material through the Earth's atmosphere, one of the most ubiquitous changes is the precipitation of tiny spinels resulting from partial melting and subsequent crystallization of the meteoritic material. These *cosmic spinels* differ from their terrestrial counterparts by their higher Mg, Ni, and Fe^{3+} contents and larger variations in composition. These cosmic spinels rapidly precipitate from partial melts produced upon meteoroid entry in the Earth's atmosphere. Because the atmosphere becomes progressively more oxidizing as the meteoroid penetrates deeper in the atmosphere, the spinel compositional range may represent a record of the ballistic trajectory of the object during its

fall to the ground and, thus, might shed some light on its provenance.

To understand better the factors controlling the spinel chemistry, pulse-heating experiments simulating atmospheric entry of extraterrestrial objects have been carried out on small samples of the well-known Orgueil carbonaceous chondrite as proxies of incoming micrometeoritic material [26]. Owing to the rapid crystallization kinetics of cosmic spinel, the Al_2O_3 content and FeO/ Fe_2O_3 ratio of the mineral have indeed been found useful to determine the entry conditions of meteoritic material in the Earth's atmosphere. As an example, spinels with high Al_2O_3 content and FeO/ Fe_2O_3 point to a very rapid deceleration and a relatively high incident velocity of cosmic spherules (Figure 8).

5 Terrestrial Versus Extraterrestrial

The classical model for the formation of the Solar System invokes the gravitational collapse of a cold molecular cloud of interstellar gas, its heating, and the formation of a central star. A flattened spinning protoplanetary disk of dust and gas surrounding the protosun extends for 100 AU or so. Initially hot, this disk later cools (T-Tauri stage). Since the heat flux is greatest close to the sun and at places where the cloud is the densest, the disk is hotter near the center and cooler farther away, suggesting a temperature decrease with increasing heliocentric distance from the protosun in the early solar nebula. On average, it is assumed that temperature drops rapidly from a few thousand degrees within 1 AU to a few hundred farther out. As the protoplanetary disk cooled down, the gas temperatures dropped below the condensation temperatures of refractory materials, like aluminates, silicates, metals, which formed in the inner Solar System at less than 1 AU. Water ice (snow line) followed suit at around 3–4 AU before other volatiles (ammonia, methane, carbon dioxide, nitrogen) farther out. Clumping of these rock/metal condensed materials into planetesimals in the inner Solar System and chunks of ice in the outer Solar System would eventually yield the actual structure of the Solar System with, in particular, its division between inner terrestrial planets and outer gas giant planets [27].

What could now be said about the differences between terrestrial and extraterrestrial materials? On Earth, basalts show a considerable variety although their chemical signatures have been inherited from terrestrial mantle rocks melted under a limited range of pressure–temperature conditions. In contrast, the chemical and isotopic compositions of meteorites indicate at least many tens of distinct parent bodies. More specifically, the diversity of achondritic (i.e. basaltic or igneous)

meteorites suggests that a significant population of such asteroid-sized bodies underwent internal melting and differentiation during the first several million years of the Solar System [28]. In this scenario, early accreting planetesimals retained sufficient short-lived radiogenic isotopes to melt partially or fully the interior except for a conductively cooled crust whose thickness was between a few and several tens of km. Material near the surface of this crust would have undergone minimal metamorphic heating and become the source region for nonmetamorphosed chondritic meteorites. Deeper material from the crust would have experienced increasing degrees of metamorphism and eventually underwent partial melting and differentiation. In this model [29], the preservation of either a chondritic or an achondritic crust on a differentiated body would thus depend on the positive or negative buoyancy of silicate melts produced at depth with respect to the overlying crust (Figure 9).

Asteroids are small, lack atmospheres, and were heated quickly by short-lived radioisotopes (^{26}Al , ^{60}Fe , etc.) instead of the much longer-lived isotopes of K, Th, and U that have mainly powered the heating of planet-embryos and planets. Relative to the Earth, their volcanic activity thus had to be very different. There are indeed large differences in the depth range over which melts form, the amount of melting that takes place in any given time interval, the rates at which melts migrate, the amounts and compositions of their volatiles, and the way in which they erupt when reaching the surface when they do so [30]. In the absence of plate tectonics, intense bombardments leading to the melting of surface materials

at scales varying from those of spherule to magma ocean make melt and glass production (and their record or signature in meteorites) even more complicated than might have been expected. Although asteroid surfaces are subjected to weathering in space by cosmic rays, solar wind implantation, or micrometeorite bombardments, their airless environment and extremely low H_2O partial pressures account for the astonishingly good preservation of their glasses despite their extremely old ages.

Finally, it is worth noticing that the recent discovery of terrestrial (rocky) exoplanets has pushed the limit of “extraterrestrial glass factories” even further away in our galaxy, since many small planets orbiting very close to their star experience intense irradiation and tidal forces so that their surfaces are mostly covered by magma [31]. Hence, they constitute a new class of celestial objects called *lava ocean planets*.

6 Perspectives

With respect to glass science, the most striking conclusion drawn from the study of extraterrestrial matter is that glass may actually be kept in its metastable state for billion years in the 170–400 K temperature interval of the lunar surface as long as water and other weathering agents are lacking. The commonly held idea that glasses would necessarily crystallize after not too long periods of time thus is clearly invalidated. On the other hand, the chondrules of primitive meteorites have experienced aqueous alteration of their metal and glass phases within

Figure 9 Sketch of silicate melt ascent in planetesimals. Moderate radiogenic heating leads to formation of free volatile phases. Most volatiles are efficiently removed via Darcy flow, resulting in volatile-poor silicate melts, whose buoyancy depends on bulk composition. Melts of CV and CM carbonaceous chondrites are negatively buoyant, leading to preservation of an achondritic crust. On the other hand, enstatite chondrite melts are likely to breach the surface; ordinary chondrites are an intermediate case [29].

their parent bodies. They might thus represent valuable model systems in studies of alteration and corrosion processes at the glass–metal–clay interfaces relevant to the long-term evolution of nuclear waste-glass packages under geological repository conditions [32]. The same would apply for predictions of elemental mobility upon alteration in anoxic environments, which are relatively rare on Earth.

From a cosmochemical standpoint, extraterrestrial glasses will bring more key information on the evolution and activity of the Solar System, thanks to their varied compositions and conditions of formation and their exceptionally long-term durability. Glass (melt) compositions will, for instance, be used as thermochemical and isotopic sensors of the gaseous environment within which these materials formed. In particular, glass compositions should exert strong constraints on the nebular gas composition itself (i.e. partial pressures, isotopic signatures) in the regions of the protoplanetary disk where chondrules formed.

The most important transformation undergone by a magma is its solidification upon cooling. The process is complex, however, if the heat released upon crystallization causes partial remelting of the material. Hence, ascertaining the processes that eventually gave rise to a sample made up of crystals, glass, or a mixture of glass and crystals can be difficult. Determinations of time–temperature–transformation diagrams for selected extraterrestrial glasses (chondrules, green glass, etc.) will thus be an important task to determine the cooling/heating rates and thermal histories experienced by chondrules and, then, to characterize their peculiar environments of formation in the solar protoplanetary disk.

Regardless of the details of the processes, an important feature is that much energy has been available during the lifetime of the Solar System through large-scale gravitational instability in the disk, accretion, short- and long-lived radionuclides, and collisions for transforming dust clouds into km-sized planetesimals, then into 1000 km-sized planet embryos and, eventually, the real planets. From its tumultuous birth to the relatively quiescent present day, the Solar System has therefore hosted a plethora of environments in which conditions have been suitable for producing partially molten materials, liquids, and magmas, and depending on their cooling history, pyroclastic flows, basaltic lavas, or plutonic rocks [3].

7.2

Geological Glasses

Cristina P. De Campos and Kai-Uwe Hess

Earth and Environmental Sciences, Ludwig-Maximilians-Universität, Munich, Germany

1 Introduction

In the solar system natural processes have been producing glasses ever since its beginnings 4.5 billion years ago (Chapter 7.1). On Earth, in particular, they have done it since time immemorial with the well-known processes of casting, blowing, and even drawing. As a striking example, nature has been producing SiO_2 glass in several ways, whereas this material was first produced artificially only in 1813 [1]. Unknowingly, man has thus been imitating nature, but at a scale that, even today, remains modest. Whereas the annual world production of glass is about 100 million tons, it represents only about 1/1000th of the total amount of magma reaching the Earth's surface every year. Even though only a fraction of the magma vitrifies, it does represent a very large volume of naturally produced glasses.

Nature also pioneered low-temperature processes that remain to be duplicated artificially. A case in point is the extremely pure amorphous silica synthesized by the unicellular diatom algae for their tests or by a great many sponge species for their spicules. Because these materials are dealt with in Chapter 8.1, here we will restrict ourselves to purely inorganic glasses. Their compositions, textures, and geological occurrences point to widely different heat sources. By far the most common and abundant glasses originate from the Earth's interior so that they provide unique insights into a variety of magmatic and volcanic processes. Other natural glasses derive from heat sources from the atmosphere or space. As such, these glasses give valuable clues about phenomena that now seldom occur at the Earth's surface but could have been much more frequent in a distant past.

Because geology is first and foremost a historical discipline whose goal is to reconstruct the evolution of the Earth since its formation, the main purpose of this chapter will be to briefly depict information that can be drawn on Earth's significant events from the study of natural glasses. As a preamble, the compositional diversity of natural glasses will be reviewed. Attention will then be paid to two forms of almost pure silica glass, *fulgurites* and *Libyan Desert glass*, melted by lightning and approaching extraterrestrial bodies, respectively. Their source is mostly quartz. Resulting from the impact of large meteorites, *tektites* with their more varied compositions will also be dealt with. Next, we will consider the predominant magma-related glasses. As a matter of fact, all volcanic rocks contain some glass with a proportion that increases with the viscosity of the melt. This proportion is thus relatively low in the SiO_2 -poor basalts but can reach >90% in the SiO_2 -rich obsidians, which gave these glasses a very great practical importance before the invention of glassmaking (Chapter 10.1). Because natural glasses interact with their environment, we will also summarize the early physical and chemical transformations they may undergo, once they have formed, referring to Chapter 7.3 for a detailed description of the corrosion reactions that eventually convert them into completely new phases.

2 Compositional Diversity of Natural Glasses

The composition of geological glasses is generally complex. There are about 10 *major* elements with contents higher than 0.1 wt % as expressed in terms of oxides (Table 1). Virtually the whole periodic table is also present, but most of the other elements are usually not considered because of their vanishingly

P ₂ O ₅	0.2	0.2	0.1				0.0–0.01			

Basalt₁ and basalt₂ are MORB glasses. La/Sm ratios range from 0.67 to 0.75 [2]; basalt₃ MORB [3]; phonolite, rhyolite, fulgurite, Rochechouart (P. Richet, pers. comm.); obsidian [4]; Libyan glass: K/U from 41 to 219, Zr/Hf from 37 to 60, Zr/U from 137 to 304, La/Sc from 6 to 13, Ir from 0 to 0.2 ppm, Cr from 1.8 to 10.4 ppm [5]; Sr⁸⁷/Sr⁸⁶ isotopic ratios for tektites: 0.718–0.724; Obs.: total may differ from 100% due to missing components (mainly water), iron oxidation state and normalization; FeO_t is the total iron content as Fe²⁺.

Figure 1 Compositions of natural glasses in the simplified total alkalis vs. silica diagram: ranges of volcanic rocks (grayish fields) and most common evolutionary trends (arrows). Some particular compositions indicated for convenience: R, Rochechouart; Ob, obsidian; Tk, tektite; Lg, Libyan glass; F, fulgurite.

low concentrations. Exception is made for a variety of *trace* elements whose contents can be only a few to around 1000 ppm, however, because their concentrations vary much more than those of major elements as a result of a greater sensitivity to the processes that come into play between original melt formation and eventual vitrification. In this way they represent fingerprints of geological glasses having similar major element contents, which are, for instance, extensively used in archaeometric studies of obsidians to identify their sources and to investigate trade in Prehistory (Chapter 10.1).

On close inspection, however, it appears that the concentrations of major elements do not vary randomly from one glass to another. Broadly speaking, increases in SiO₂ contents are related to decreases in alkaline earths and increases in alkalis. These variations are strongly correlated as illustrated by plots of SiO₂ contents against Na₂O + K₂O for the most common volcanic rocks and glasses (Figure 1). From the primary SiO₂-poor to the most evolved SiO₂-rich compositions, the impressive diversity of magmatic products can thus be reasonably well described with just a few parameters. There are nonetheless clear

exceptions to those trends characterized by extremely high SiO_2 contents. They will be described first in view of this chemical simplicity.

3 Fulgurites: The Petrified Lightnings

Fulgurites are famous in Sahara. Their compositions are there very close to that of pure silica (Table 1). They are found on sand dunes, generally in the form of fragile hollow pieces 5–20 mm in diameter and typically ~10 cm long (Figure 2a), and which are in fact fragments of tubes whose original length can reach a few meters. Occasionally, they are also found as small beads. Their widespread occurrence in sandy deserts points to rather common melting events. Lightning (*fulgur*, in Latin) is their obvious source, causing such high temperature rises ($>1600^\circ\text{C}$) that quartz grains may melt or even vaporize to create hollow, channel-like structures. The morphology of the fulgurite tubes then indicates the lightning pathway along which quartz melted on the ground.

Actually, a typical lightning involves a current of 30 kA and an energy of 500 MJ. Since the enthalpy of fusion of quartz is 9.4 kJ/mol [6], a single strike could cause the melting of 3000 tons of this material. Even when taking into account branching of the lightning on its way to the surface, one concludes that only an extremely small fraction of the energy is expended to melt and vaporize sand. Clearly, the rate of heat transfer is the limiting factor of the process since the lightning energy is released in a fraction of a millisecond at most. The small diameter of the glass tubes, within which the melt was vaporized and on which sand grains are glued, is thus distinctive features of fulgurites resulting from this brevity. This amorphous silica, named *lechatelierite* (after Henry Le Chatelier [1850–1936] known in particular for his moderation principle in thermodynamics), exhibits typical flow structures and vesicles.

To be most efficient, the transformation would require powdered starting materials. In nature, however, silicate sand is found mostly in the form of quartz, one of the most stable minerals at the Earth's surface. Thanks to its lack of cleavage, high hardness, and low solubility in aqueous solutions, it may accumulate under the action of wind or water but has too high a melting point and is too viscous when melted to yield a bulk glassy phase. A lightning strike can in contrast melt any silicate rock partially or even totally when the liquidus temperature is much lower than that of quartz, especially if the rock is fragmented as found in explosive volcanism (Figure 2b). One then obtains a *rock fulgurite*, but the small amounts of glass produced in this way often quickly disappear through alteration, which makes them difficult to observe.

4 Impact-Related Glasses

4.1 Impactites

As indicated by its name, Libyan Desert glass (Figure 3) originates from a restricted area of Sahara where it formed 28.5 million years ago. It is found on quartz sand dunes as clear, pale, yellowish scattered fragments with a size of up to a few hundred grams. The Egyptians valued this rare and beautiful material and used it, for instance, on the pectoral chain of Tutankhamon (Cairo Museum, Egypt) to make the yellow-green scarab at the heart of his pendant [7].

This clear, shiny glass carries few inclusions (Figure 3) and also has a unusually simple composition with a SiO_2 content ranging from 97 to 99.3 wt % (Table 1), which makes it not only translucent but also transparent. In addition, the bigger size of the samples, when compared with fulgurites, and their wide scatter indicate that the melting event was of a much longer duration and larger spatial extent, whereas the well-polished surface of the glass caused by sand blasting points to a not so recent event. As for the lack of any sharp crater observed in the region, it should exclude the impact of an extraterrestrial body as the heat source.

Two other explanations have been proposed, involving the disintegration of either a comet or a meteorite at an altitude above the ground low enough to cause rather large amounts of sand to be melted by the heat released in the atmosphere by a shock wave, but high enough to blast this melt and disseminate it over a few thousands of km^2 .

Clues on the origin of the Libyan Desert glass have been provided by a small carbon-rich stone found in the same region, in which patches of sub- μm diamond represent spectacular evidence for the attainment of very high pressures. Along with the results of isotope analyses, this feature has been interpreted as indicating that Libyan Desert glass formed upon the burst caused by the explosion of part of a cometary nucleus after its entry in the atmosphere had caused the loss of volatile hydrocarbons and ice and the intake of heavy noble gases (Ar, Kr and Xe) [8]. The rare-earth element contents of Libyan glass, i.e. La/Y ratios from 6.5 to 10.9 [5], do point to desert sand as the source material, but magnesium enrichments of up to 0.5 wt % (Table 1) require an admixture of chondrite meteorite material (Chapter 7.1) to be explained. Some additional rare trace elements such as Co, Ni, and Ir have also been found in desert glass in similar proportions as in chondrites [5].

The uniqueness of Libyan Desert glass thus does not seem to result so much from the negligible fraction of the Earth's surface covered by sandy deserts, but mainly from the fact that disintegration of a comet

or meteorite well above the ground should be very rare. The well-known occurrence of the Tunguska event [9] on 30 June 1908 when 2000 km² of forest were wiped out in Siberia without leaving any

observable trace of extraterrestrial matter supports such an interpretation. In this case, however, agreement has not been reached yet on the nature of the incoming body.

Figure 3 Libyan Desert glass, with polished surface produced by sand blasting under strong winds. The small inclusions are impurities from the melted sand or tiny fragments from the impacted cosmic material.

4.2 Tektites

As discovered only in the twentieth century, glasses named *tektites* (from the Greek *tēktos*, molten) may be also produced by large meteorites impacting the Earth. They are usually very dark in color (black, brown, greenish) with a size ranging from a few to several centimeters. Lighter colored and transparent tektites such as *Moldavites* are exceptionally rare. These may be emerald green with bubbly inclusions. Although related to Libyan Desert glasses, tektites differ markedly from them in their chemical and isotope compositions that closely resemble instead those of upper continental crustal rocks (Table 1).

They are found on the ground or at some depth. From their compositions, they have been grouped in four distinct *strewn fields* in North America, Central Europe, Western Africa and Australia/Asia. Whereas the third one is more or less restricted to Ivory Coast, the last is really large since it extends from Tibet to Australia, covering approximately one third of the Earth's surface. By far, tektites from this Australasian strewn field thus are the most common.

Because of their very low water contents and very reduced iron states, implying melting temperatures higher than 1700 °C, tektites are considered to be molten terrestrial ejecta, which have been originated by the hypervelocity impact of a cosmic body (meteorite) hitting the Earth's surface [5]. The splashed form and shallow bowl aerodynamic shapes of tektites are due to ablation of molten material in the atmosphere and in addition evidence their ejection into the stratosphere (Figure 4).

4.3 Other Impact Glasses: The Example of Rochechouart Pseudotachylites

Even though the presence of typical lavas in the Rochechouart area in central France was observed as early as the late eighteenth century, no trace of a volcano was ever

Figure 4 Tektite from the Australasian strewn field. Aerodynamic shape resulting from ablation of molten material upon reentry in the atmosphere after ejection into the stratosphere.

found there. For good reasons, since it was established in 1969 that melting was actually produced by a meteorite impact 200 million years ago when F. Kraut discovered the first shocked quartz under the microscope in local rock samples.

Along with previous field observations on a variety of impact structures around the world (e.g. the Nördlinger Ries, in Germany, the Meteor and Sudbury Craters, in the USA, the Chicxulub crater in Yucatan), experimental laboratory work on friction melting has shed new light on the origin of structures such as Rochechouart. In particular, it has been demonstrated that shock waves may cause rock fragmentation (*brecciation*) and local temperature rises eventually leading to melting. Impacted rocks may be recognized by macroscopic and microscopic features. Planar deformation in rock-forming minerals and the presence of high-pressure mineral polymorphs (e.g. coesite and stishovite from quartz or diamond from graphite) are strong evidence of high-pressure and shock waves in the so-called *diaplectic* glasses. These changes result from pressure-induced amorphization at low temperature (Chapter 3.10) and of “normal” glasses formed through actual melting [5].

Recent detailed studies in melt and clasts from a vein system containing melt rock and hydrothermal crystallization from the Champagnac quarry (Rochechouart structure), however, revealed new aspects regarding the shock phenomena [10]. There the melt fraction was actually produced by friction during lateral shear movements after the impact. Circulation of hydrothermal fluids (up to 700 °C, high P_{H_2O}) then caused the plagioclase feldspars of the breccia clasts and immediate host rocks to transform into mica. Long-term tectonic activity (crosscutting fractures) and additional hydrothermal

Figure 5 Pseudotachylite as formed by melting of a gneiss (consisting mainly of quartz and feldspar), along mostly linear planes of stress concentration. Frictional melt reintruding the source rock and suggesting a relatively high viscosity through the lateral variation in thickness and morphology (Silvretta, NW side of the Unterengadiner tectonic window, Swiss Alps, collection of the Museum Reich der Kristalle, Munich).

modifications took place, which induced later partial devitrification of the glassy matrix.

Since the compositions of these glasses depend on the source rocks, they may be highly variable even within the same impact structure (Figure 1; Table 1). They include in particular *pseudotachylite* (from the Greek *takhys*, swift), which are friction-melted glasses [11] whose name distinguishes them from *tachylites*, the basaltic glasses formed in conspicuous volcanic terrains. Pseudotachylite is black and consists of angular and rounded wall rock fragments enveloped by a microcrystalline to glassy matrix (Figure 5). When these rocks are affected by a high stress field and additional mechanical rebound, part of the deformation energy is transformed into so much heat that the material partially or completely melts and the resulting liquid is injected along fractures. The compositions of the glasses then simply reflect those of the total or partial melting from parent rocks.

When such glasses are found in nature, they reveal that a pre-existing natural material has been affected by a high stress field and additional mechanical rebound. So, pseudotachylites can also be formed in volcanic edifices [11] or, more generally, when melting is observed along a normal or inverse fault plane [12]. The presence of pseudotachylite thus provides quantitative information on the tectonic forces involved in the process. Frictional melting of natural rocks has been simulated in the laboratory through the frictional slip of two rock surfaces at high velocity rates (~ 1.3 m/s). The conclusion is that stresses of around 10 MPa and slip distances

lower than 15 cm are required to ensure rock melting [11].

5 The Basalt Factory

5.1 The Ubiquitous Basalts

The most common volcanic rocks on Earth are basalts. They typically have SiO_2 contents ranging from 48 to 52% (Table 1). Most basaltic magmas are erupted along 60 000 km of mid-oceanic ridges and hot spots, where they continuously produce not only new oceanic floor but also archipelagos and islands such as The Azores, Hawaii, Iceland, or La Réunion. They are in addition found in continents where erupted volumes of millions of km^3 have given rise in the past to the immense plateaus of Dekkan, in India, or Paraná-Etendeka, in Brazil/Africa. They are very fluid thanks to their relatively low contents of the network-forming elements Si and Al (Table 1), which allow them to ascend rapidly to the Earth's surface without cooling down too much along the way. With a viscosity of the order of 100 Pa·s, they are still very fluid at typical eruption temperatures of about 1200 °C so that they can flow rapidly down the slopes of the volcano where, depending on relief and erupted volume, they can travel up to a few tenths of km before coming to a rest. On the other hand, the viscosity of the melt increases when the lava cools down, but the main factor is crystallization. Magnetite (Fe_3O_4) generally precipitates first

Figure 6 Pelé's hair and tears (small black droplets) from the Piton de la Fournaise volcano. Source: Photo P. Richet.

and then serves as nucleating sites for other minerals such as pyroxenes. In the end crystals with a variety of shapes and size are observed within a residual glassy matrix [13].

5.2 Pelé's Hair and Reticulite

When an eruption of fluid magma gives rise to the high lava fountains that have been popularized by films and videos, with a little bit of luck one can find on the ground glass fibers from 1 to 500 μm thick known as Pele's hair (from the name of a Hawaiian goddess) (Figure 6). These were first described at the Piton de la Fournaise (La Réunion island) by Bory de Saint Vincent in 1804. Except for somewhat larger diameters, they are strikingly similar to industrially produced rock wool fibers (Chapter 9.3), showing also the presence of entrapped globules of non-drawn glass. They are simply drawn hydrodynamically at the eruption event where the lava jet can reach speeds over 35 m/s. Why are such high speeds achieved? The answer is that exsolution of gas (mainly water) upon decompression during magma ascent is the driving force of volcanic eruptions. The presence of bubbles not only increases the buoyancy of the melt and bubbles but also exerts such a hydrodynamic ascending force that the magma gets fragmented even before reaching the surface and being stretched as fibers. Even though Pelé's hair are common products of volcanic eruption, their intrinsic fragility and high surface/volume ratios make them sensitive to weathering so that they rapidly disappear.

Glass blowing is the other process at work with such fluid magmas. Taking place at all scales when gas bubbles grow upon decompression, it is actually revealed in many volcanic rocks by the presence of bubbles. In some cases,

Figure 7 Reticulite from unknown origin. Source: Photo P. Richet.

the volume fraction of bubbles is so large that the material can be considered as a frozen in foam called *reticulite* (Figure 7). When very large bubbles explode, very thin glass membranes can form. But they are even more fragile than Pele's hair.

5.3 Water-Quenched Glasses

Quenching is definitely faster and most efficient when a melt is poured in water. In lavas the proportion of glass thus is the highest for submarine or lacustrine eruptions. A typical *pillow-lava* morphology, resulting from the rapid vitrification of the surface of the advancing flow, can be observed. Over a thickness of a few mm to cm, an essentially *tachylite* phase is thus preserved. The pillow lava has a glassy crust including only very tiny crystals, below which the proportion of glass decreases to reach the typical 50% fraction of basalt. Given that about 75% of magma erupt as submarine basalt, these glasses are by far the most abundant that form at the Earth's surface. As a result of rapid quenching, however, the glass surface is under tension or highly stressed. It allows bacteria and other organisms such as sponges to take advantage of it, either to leach out cations or induce changes in the iron oxidation state, which could have been a potential energy source for early life [14]. As described in the following chapter, however, the glass from a pillow lava rapidly transforms to other phases upon reaction with either fresh or seawater. Finally, one can note that basalt glasses are also called *sideromelane* (from the Latin *sider*, star, and Greek *melanos*, black).

5.4 Columnar Jointing: The Role of the Glass Transition

In an aerial environment a striking feature of volcanic rocks is *columnar jointing*, whereby a thick enough lava flow fractures upon cooling to form rather regular polyhedral prisms, generally pentagonal or hexagonal, perpendicular to the upper (the air) and lower (the ground) cooling surfaces. That they are most often observed for basalts is simply because of the more frequent occurrence of these lavas, but an interesting fact is that the section of the prisms tends to increase with the SiO_2 content of the lava. The similarity of the shape of the columns to those of crystals forming in aqueous solutions leads early eighteenth-century geologist to assume that volcanic rocks precipitated from a primordial ocean. When N. Desmarest demonstrated in 1763 that basalt was actually a volcanic rock, then the occurrence of columnar jointing became, at once, an infallible indicator of former volcanic activity. It thus played a major role to demonstrate that volcanism was a major geological agent and not the accidental phenomenon indicated by the existence of the limited number of active volcanoes known at that time.

Among the most famous examples are those from the Giant's Causeway in Northern Ireland. We examined under a microscope thin sections of samples taken from such a column. As may be expected from faster cooling in the vicinity of the fractures, one observes a clear increase in crystallinity from the border to the middle of a column (Figure 8). In some 10–15 cm the texture changes from a predominantly glassy matrix with only few crystallites to an almost fully crystallized rock with the same composition.

Although the manner in which columns form is not yet fully understood, the phenomenon is a striking illustration of the changes in thermal expansion that take place at the glass transition. In some respect, the phenomenon is similar to the accumulation of internal stresses within a glass piece that is not annealed. The difference here is that fractures take place in a regular way because the presence of crystals prevents them from propagating in directions parallel to the cooling surfaces. It has been found that the column radius and fracture size are proportional to each other and inversely proportional to the cooling rate of the lava [15]. The thermal expansion at the liquid–glass transition decreases more for SiO_2 -poor than for SiO_2 -rich lavas. It implies that the stress accumulated increases and, in agreement with observations, that the section of the columns decreases correspondingly.

Figure 8 Crystallinity contrasts in columnar basalt as seen in thin sections cut perpendicular to the vertical axis. (a) Low crystallinity at the border of the column (photomicrograph under natural light). (b) High crystallinity near the center (photomicrograph under polarized light). Sample from the Giant's Causeway, Northern Ireland.

6 Siliceous Glasses

6.1 Pumices: Bubble-Rich Glasses

When observed under the microscope (Figure 9), volcanic products generally show void or bubbles, crystals, and an apparently glassy matrix with dark and light brown portions. The former portions contain tiny crystals, invisible under this magnification, which partially absorb light but is mostly crystal-free and therefore isotropic and translucent. In view of crystals dispersed in a

Figure 9 Coexisting crystals, glass and bubbles in a rapidly quenched lava fragment from Croscat volcano (Catalonia, Spain). Photomicrograph under polarized light C. Cimarelli.

glassy matrix, volcanic rocks might be considered as glass ceramics but of a special kind because of the presence of voids.

Among volcanic products pumices are readily distinguished by their density that can be as low as 0.7 g/cm^3 , which allow them to float on water (a feature that long ago allowed sailors exploring uncharted seas to know that some island was to be found nearby). Such low density of course originates in a very high vesicularity where voids are mostly interconnected because they represent the leftovers of the gas that was contained in bubbles before their eventual escape. Whether microcrystalline or crystal-free (Figure 9), the silicate matrix of pumices thus represents another example of glass blowing upon exsolution of volatile components during magma ascent and eruption. With respect to reticulite, the main difference is a higher magma viscosity mostly related to a higher silica contents (Table 1). Pumice formation thus points to more explosive eruption styles where vitrification is related to volatile release caused by decompression at the top of the fragmentation layer (Figure 10). Industrially, pumices are extensively used, for instance, as abrasives thanks to the sharp edges constituted by the thin walls separating

the bubbles. They are further used in agriculture, civil construction, and house building.

6.2 Obsidians

Because glass formation depends so much on cooling rate, under favorable circumstances, almost pure glasses can form as large blocks for SiO_2 contents that can be as low as about 60 wt % in special cases. This is why the term *obsidians* denotes natural glasses with a significant range of compositions. As extensively discussed in Chapter 10.1, the unique properties of obsidians made them extremely valuable before metallurgy was born. Obsidians have esthetic properties that make them valuable as ornaments. However, the most important property of obsidian is to break up macroscopically without developing straight planar surfaces but rather smooth, curved bowl-shaped surfaces, the so-called conchoidal cleavage (Figure 11). Upon magnification, however, sharp edges become visible. They have been investigated in fragmentation experiments made under controlled compressional stress regimes [4]. Newberry obsidian, from Oregon, is, for instance, flow banded on a mm scale with less than 1 vol % crystals (iron oxide microlites). Lacking both grain boundaries and a connected porosity (<2% vesicles), it gives rise upon controlled stress to sharp blade edges that do not look jagged even when observed under an electron microscope (Figure 12). Interestingly, these remain straight down to a thickness of only 3 nm, which makes them about hundreds of times sharper than the sharpest steel blade known. Hence such *Stone Age* obsidian tools are still in use for biological and medical research purposes.

The presence of microlites in obsidian has in contrast strongly detrimental effects on blade sharpness and also on uses as ornamental stones. Exceptions are *snowflake* obsidians, in which scattered flakes of white feldspathic crystals are found; *fire* obsidians, which owe their names to tiny iron oxide inclusions (Figure 11); and *rainbow* obsidians with multicolored optic effects. Like chemical composition, the nature and proportion of crystals in obsidian depend on the peculiar geophysical and thermochemical conditions under which the magma formed, evolved, and eventually cooled. Complete characterization may thus require a combination of analytical techniques such as SEM, TEM, and EDS analyses (Chapter 2.3) along with studies of cleavage, fracture, and etching patterns, which are considered to help greatly in more complex cases.

In archeological studies, what matters most is the trace element content of the obsidian because it can be highly variable even for samples coming from a relatively small

Figure 10 Bubble generation in a volcanic conduit (at the top of the fragmentation layer) from volatile exsolution induced by decompression during an explosive eruption. *Source:* Modified after S. Mueller [16].

geographical area (Table 2). It is this high chemical variability that allows the origins of obsidians to be tracked. Referring to Chapter 10.1 for various case studies of the provenance of prehistoric artifacts, we will present here

Figure 12 Blade edges from a lab compressed banded obsidian. Tiny lighter points are iron oxide microlites (<1 vol %). BSE image shows high homogeneity: no grain boundaries and lack of connected porosity (original gray BSE image from S. Kolzenburg).

the interesting example of a mosaic of the Church of St. Juvenal in Umbria (Central Italy). In fact, the obsidian tesserae of the mosaic depicting the “Majestas Christi” come from the Monte Arci deposit, in Sardinia. This material matches and has been reused from another church (the Cathedral of Narni) in the St Juvenal mosaic [17]. Such a recycling is very common in medieval artifacts and greatly complicates the dating of obsidian-crafted objects.

7 The Fate of Natural Glasses

Lunar glasses have been preserved in a pristine condition ever since their formation billion years ago thanks to the moon's extremely dry environment (Chapter 7.1). On Earth, geological glasses are inevitably subjected to the corrosive action of atmospheric and underground agents. In this respect, an interesting feature is that, by diffusion processes, volcanic glasses can slowly dissolve small but significant amounts of water at ambient temperature and then persist in an amorphous state from tens to hundreds of million years. These glasses are then called

perlites or *pitchstones*. Although the literature on the formation process is scarce and contradictory, the current consensus is that the water content in the ground mass remains lower than 1 wt % in obsidians, whereas it is higher than 2 wt % in perlites and from about 5 to more than 10 wt % in pitchstone.

The physical boundary between obsidian and perlite is distinct and sharp as seen in the macroscopic features of "Apache's tears" (Figure 13). Perlites and pitchstones actually show a characteristic "perlite" texture, which comprises a curved or spherical crack network in the glassy matrix. The fractured glass

Figure 13 Apache tears: a perlite with obsidians inclusions from Superior, Arizona, USA. Perlites show a characteristic “perlitic” texture with a crack network in the glassy matrix. Obsidian is dark with typical shiny brilliancy. Source: Sample courtesy A. Gilg.

fragments in the cracks are often completely devitrified. Occasionally, one can in addition detect decreases in water concentration from the rim (next to the cracks) to pristine obsidian. The formation of the crack network and its subsequent hydration is interpreted as resulting from cooling of the melt in a submarine environment.

The high fracture density and surface area of perlite and pitchstone make these volcanic products ideally suited for simultaneously holding water and air pockets. This dual ability of aeration and water retention is directly put to use in various industrial applications. Like natural pumice, processed perlite and pitchstone are used as soil amendment in horticulture or as filler in the construction industry. In addition, perlite has found applications in the building industry. Upon heating, the glass transition is crossed at around 770 °C above which water exsolution and bubble growth take place to create a foamy network. The result is a very lightweight product with more than 10 times its original volume, which is used especially for insulation and as a component of lightweight concrete.

In the presence of water, the least evolved glasses (basaltic composition) devitrify in a complex manner. The end product consists of a mixture of residual basaltic glass and dominantly clay minerals, such as smectite and zeolites [18]. The contribution of microorganisms in the process is still open. The issue is important because there is evidence for glass bioalteration dating back to 3.5 billion years [14]. If it were confirmed, this result could mean that some of the earliest microorganisms used the thermodynamically unstable state of basaltic glasses

as an energy source. In this way, the glass alteration process would have constituted a foundation for very early life.

8 Compositional vs. Rheological Variability

In view of the rather simple compositional trends defined by geological glasses formed by cooling of liquids (Figure 1), it is appropriate to conclude this review with a brief discussion of *magma differentiation*. Magmas originate by partial melting of deep rocks under different conditions of temperature, pressure, and fluid content. By far the most important are *peridotites*, which are mainly made up of $(\text{Mg,Fe})_2\text{SiO}_4$ olivines and $(\text{Ca,Mg,Fe})\text{SiO}_3$ pyroxenes (cf. [13]). In mid-ocean ridges or in some continental contexts, such *primary* magmas ascend directly to the Earth’s surface as indicated by the peridotite nodules often carried up as inclusions in basalts. Upon slower ascent, however, magmas may reside for possibly long times in magma chambers where they alternatively crystallize partially first into olivines and pyroxenes. The residual liquids then become enriched in Si, Al, and alkalis so that its composition drifts from SiO_2 -poor basalt toward SiO_2 -rich rhyolite (Figure 1).

The input of new primary magma from the mantle and the coeval assimilation of enclosing rocks are additional factors changing the composition of natural melts. During emplacement up to the surface, other rocks and sediments may also be incorporated, partially melted, and merged into the original magmatic system. The interplay

Figure 14 Viscosity range (in log units of Pa·s) for natural magmas and some remelted materials. Compositions from [19]. Viscosity calculations after [20]. The upper diagram (a) shows viscosity calculations of water-free melts. The diagram below (b) shows same compositions with 1 and 5% of water dissolved in the silicate melts. Temperature in °C. Normal magmatic temperature conditions are below 1200 °C.

between all these processes, therefore, leads to coeval convection and diffusion processes (mixing) and to further complex differentiation. Primary or primitive magmas from the mantle evolve to produce the whole range of compositions presented on Figure 1, including natural glasses and the wide range of natural terrestrial volcanic rocks.

The compositional range of geological glasses is, therefore, bracketed by basalt (e.g. Pelé hair and reticulite) and rhyolite (e.g. obsidians and pumices) in (Figure 1). Intermediate glass compositions are found mainly in pumices and in matrix components of other volcanic rocks (andesite, trachyte, and phonolite). As glass ceramics, they do not exhibit the cleavage and optical properties of obsidians. If their uses remain restricted to building purposes, they are nevertheless of great interest for petrologists, who pay attention, in particular, to their glassy matrices.

The compositional evolution of magma of course translates into very large viscosity changes and thus greatly affects the glass-forming ability of the magma and its eruption style. Basaltic glasses only form under abnormally high magma production and/or high cooling rates. High rates are achieved either with water cooling in lakes or in the sea or when extensive fragmentation takes place in air and increases the surface to volume ratio. At the other end, less fluid magmas rise more slowly and thus cool down more on their way to the surface. They may reach it at temperatures of only 800 or 900 °C, at which

their viscosity can be as high as 10^8 Pa·s so that bulk vitrification becomes possible if liquidus temperatures are in addition not so high. This is actually the case for obsidians. At a microscopic level, the special properties of obsidians are related to the predominance of Q^4 species in their structure, which is thus a three-dimensionally interconnected network of SiO_4 tetrahedra.

These effects are enhanced by volatile exsolution because water depresses viscosity much more near the glass transition than at superliquidus temperatures (Chapter 5.5). In other words, the viscosity of the parent magmas of obsidians increases more quickly upon degassing and cooling than upon only cooling, which also favors vitrification (Figure 14).

Turning now to eruption styles and types of volcanic products, it is worth recalling that the driving force for explosive eruptions is ultimately linked to volatile exsolution and subsequent overpressurization of the growing bubbles during the rise of magmas toward the Earth surface. In fluid magmas, either at high temperatures or at low SiO_2 contents, bubbles travel undisturbed to the surface and escape, leaving no track behind. This efficient removal of the gas phase from the magma leads to a purely effusive and nonexplosive magma flow (Hawaiian activity). At moderate viscosity, bubble extraction and coalescence still take place, but gas slugs are generated and the cause of ash, bomb, and splatter production (Strombolian activity and lava fountaining).

In a highly viscous magma, pressure strongly builds up if the bubbles remain isolated. Upon rapid decompression on the way up, bubbles can then blow up and fragment the lava, leading to strong explosive volcanic events (Figure 10). The most explosive eruptions (Plinian, Pelean) and related products (pumices) are linked to such SiO₂-rich melt compositions.

9 Perspectives

Per se natural glasses do not have a fundamental importance in igneous petrology because they are found only in volcanic rocks, in which they are generally not the major phase. But their analysis will nonetheless continue to yield valuable clues onto the formation and evolution of lavas and thus on a variety of the magmatic processes that have shaped the Earth at all scales. In some respect, however, tektites or Libyan glass are unique since they reveal extraordinary events that had likely major consequences in the past on the biosphere and would have still more catastrophic effects if occurring in the modern world. As for obsidians, their importance in archaeometry does not need to be stressed again.

Perhaps not so well known in glass circles is the great but indirect importance that natural melts have acquired through the work consistently done by earth scientists since the late 1970s to arrive at a better understanding of structure–property–composition relationships [19], especially for viscosity and density. Given the almost unlimited natural conditions of chemical composition, temperature, and pressure, such work is not only a prerequisite for any serious petrological applications but is also valuable in a variety of industrial applications for which high-quality physical data are needed (e.g. Chapter 1.7). In addition, natural glasses are of course extremely valuable model systems in studies of long-term glass stability especially with respect to corrosion by aqueous solutions in the contexts of municipal (Chapter 9.9) and nuclear (Chapter 9.10) waste storage.

Concerning practical applications, natural glasses such as pumices and pozzolans [21] will continue to be used as inexpensive abrasive or porous materials. Their hydraulic properties are also likely to be more extensively exploited in cement production [21]. As part of volcanic rocks, natural glasses will also be more used as more environmentally friendly raw materials, for example, in the production of insulation fibers where the presence of iron is in fact required and not avoided (Chapter 9.3).

7.3

Corrosion of Natural Glasses in Seawater

Roland Hellmann

ISTerre, CNRS, Université Grenoble Alpes, 38058 Grenoble Cedex 9, France

1 Introduction

The chemical alteration of natural volcanic glasses plays a major role in controlling seawater chemistry [1] and aqueous CO_2 uptake during dissolution [2]. Of particular importance is the chemical alteration of basalt (Chapter 7.2) that makes up much of the oceanic crust. Rapid quenching of magma by seawater, in particular at mid-ocean ridges (MOR, the long submarine volcanic chains formed by upwelling magma at divergent plate boundaries), leads to the production of large volumes of basaltic glass. In fact, basalt glass comprises 20% of the extrusive layer of oceanic crust in the Atlantic [1].

Interaction with seawater results in chemical alteration of both basalt rock and glass, the latter being by far the most reactive phase because of its metastability. Given the volumetric importance and high reactivity of basaltic glass, its chemical alteration by seawater represents a key process in controlling the composition of oceans, and can even be considered as a proxy for chemical weathering of oceanic crust [1]. When altered oceanic crust is brought down into the mantle by subduction, the cycling of elements, including halogens and noble gases [3], is therefore in large part also controlled by seawater–basalt interactions. In addition, these interactions consume aqueous CO_2 [2], thereby making this process an important part of the global carbon cycle. Since basalt is rich in calcium and magnesium oxides, reaction with CO_2 -rich solutions can lead to extensive formation of Ca and Mg-carbonates, which represents permanent geological sequestration of carbon [4–6]. Basalt glass alteration is also important for industrial applications, in particular

as an analog process for nuclear glass corrosion over geological time scales [7].

In this chapter, the metabolic processes of microorganisms living in seafloor basalt environments are presented, many of which are related to reactions that lead to biologically mediated basalt glass alteration. A critical analysis of current models of biotic and abiotic alteration is then made in terms of the preferential cation leaching and coupled interfacial dissolution–reprecipitation (CIDR) mechanisms (Chapter 5.12). The first theory postulates that certain labile cations are preferentially released from the glass structure and replaced by hydronium ions (H_3O^+) from the surrounding fluid. The overall process, controlled by interdiffusion, results in the formation of a cation-leached, silica-rich surface layer. According to the second theory, these surface layers form by the contemporaneous coupling of congruent glass dissolution and reprecipitation of a hydrated silica surface layer. This is an interfacial chemical process that occurs within a thin fluid film of ordered water molecules bound to the pristine glass surface. In the first theory, the leached layer is characterized by broad sigmoidal cation depth profiles, whereas a very sharp chemical and structural interface separates the silica layer from the glass in the second theory.

2 From Basalt Glass to Palagonite

Bulk basalt glasses formed at the MOR generally have the same composition as basalt rock, being mainly composed of SiO_2 , Al_2O_3 , CaO , MgO , and FeO [8]. Another basalt glass type, called interstitial, is primarily composed of just SiO_2 and Al_2O_3 . It constitutes the matrix of crystalline phases within pillow basalts, massive flows, and dikes [8].

The first step in the chemical alteration of basalt glass in seawater at low temperatures generally results in the

formation of *palagonite* – German *Palagonit*, from *Palagonia*, Sicily [9]. This phase is akin to a gel and appears as a brown to yellow-colored rind forming a distinct surficial layer on the pristine glass [10, 11]. Its chemical and structural complexity has been investigated by transmission electron microscopy (TEM) and nano-secondary ion mass spectrometry (nanoSIMS) [12]. Palagonite has sometimes been specifically characterized as a hydrated, cation-depleted altered glass layer, but more often is simply considered as a surface alteration product originating from the hydration and oxidation of fresh glass, which results in a porous mix of amorphous, poorly crystalline, and crystalline authigenic (i.e. formed in situ) phases. In contrast, interstitial glass alteration may not involve palagonite formation, but rather direct formation of clays [8]. The presence of palagonite between fresh glass and authigenic phases has not always been discerned, but in many cases can be attributed to insufficient analytical resolution.

Secondary authigenic minerals, such as phyllosilicates, zeolites or Fe, and Mn-oxyhydroxides, may form on the palagonite surface either from a surrounding oversaturated bulk solution or in specific cases, through in-situ transformation of the palagonite itself. In environments with elevated temperatures (up to ~400 °C), such as those found at hydrothermal seafloor vents, a different suite of secondary phases will form. In general, precipitation of authigenic minerals within pore spaces may hinder access of seawater to the fresh glass interface, thus passivating the alteration reaction [13].

3 Seafloor Basalt Alteration by Abiotic and Biotic Processes

Alteration of basalt glass by seawater occurs by abiotic and biotic processes, but their partitioning is still not well known. The roughly 200 000 km² occupied by seafloor basalts constitute by far the world's largest continuous microbial habitat [14]. It is generally accepted that microbe–basalt glass interactions control biogeochemical budgets, as well as the cycling of many elements (e.g. C, Fe; [14, 15]) between seawater, the ocean crust, and the upper mantle. Exposure of fresh basalt to seawater results in abiotic alteration and surface coverage by epilithic (surface dwelling) microbial communities. The former process produces μm-sized dissolution features (cavities, crevices, and pores) that are then rapidly colonized and exploited by endolithic (pore-space dwelling) microorganisms [16]. The ubiquitous association of Fe and Mn-oxyhydroxides with basaltic seafloor crust arguably points to the pervasive action of microorganisms.

As with abiotic alteration, biotic processes in seawater both oxidize and hydrate basalt glasses. Exposed glassy

rinds of basaltic seafloor lavas on the East Pacific Rise, for example, are characterized by a distinct microbiome made of up to 10⁹ cells of Proteobacteria (88–96%) and Archaea per gram of rock [17]. This abundance is 10³–10⁴ times greater than in adjacent overlying seawater [17]. The distinct nature of basalt microbiomes is also evidenced at Arctic spreading ridges [18] and the Juan de Fuca ridge flank [19]. In general, the predominant bacterial phylum is variable and depends not only on local conditions and specific mineralogy but also on the age of the basalts [18], possibly through an effect related to the degree of alteration.

The importance of abiotic and biotic alteration is likely similar up to 90 °C [20], beyond which the survival rate of microorganisms falls off. Estimates indicate that 70–80% of all glass alteration is biologically mediated within the upper 250 m of the ocean crust, whereas this process becomes minor (<10%) at depths greater than 500 m [13].

Colonizing microbes create two principal types of micro-scale textures [21]: (i) granular clusters emanating from crack walls, characterized by 0.5–2 μm-sized nearly spherical voids that are often filled with authigenic clays and Fe-(oxy)hydroxides [13]; (ii) less commonly, worm-like tubular structures [22], a few μm in diameter and up to 100 μm in length. The latter can often have complex spiral geometries [13]. It has been proposed that biotic alteration starts with granular dissolution, which can eventually be superseded by tubular alteration [23]. Interestingly, basalt glass weathering in a subglacial environment on Iceland is also characterized by spherical vesicles, with granular clusters extending from palagonite rind into the fresh glass [24]; however, very elongated tubes and long channel structures apparently do not form.

4 Alteration Enhancement by Microorganism Metabolic Processes

Given the absence of sunlight, bacterial and archaeal assemblages in contact with seafloor basalts derive their energy from chemical reactions involving inorganic compounds, and their carbon from inorganic sources. These *chemolithoautotrophic* reactions are the basis of biomass production and microbial diversity [17]. Two principal types of metabolic chemical processes take place. The first is biotic methanogenesis [18, 19], which is mediated exclusively by Archaea with specific enzymes [25]:

where CO₂ actually exists as HCO₃[–] in deep sea environments. The source of H₂ can be either microbial or inorganic (the latter either by water radiolysis or by serpentinization reactions of olivines and pyroxenes;

[25]). Methanotrophic bacteria and Archaea will, in turn, partially consume the methane that is produced [25]. Redox reactions are the basis for the second type of metabolic process: oxidation of iron [17, 18], manganese [15], and sulfur [17]; reduction of sulfate [19], iron, and manganese [18]. Basalts are composed of minerals rich in reduced metals, such as Fe^{2+} and Mn^{2+} , as well as of minor amounts of metal sulfides (S^{-2}); all of these reduced elements can serve as electron donors for chemolithotrophic communities. Enzymes, which are macromolecular biological proteins found in cellular membranes and cytoplasm, play a pivotal role in speeding up chemical reaction rates that are vital for the metabolic activity of microorganisms [26].

The important question is how metabolic reactions of microbes chemically alter and dissolve basaltic glass. Part of the answer is that abiotic and biotic processes work in tandem, but generally at different rates. Abiotic dissolution of basalt glass under deep seafloor conditions, i.e. low temperatures and circumneutral to weakly alkaline pH conditions, is slow but nonetheless effective in releasing basalt cations, namely Si, Al, Ca, Fe, Mn, and Mg. Once released into solution (seawater), reduced metals such as Fe^{2+} and Mn^{2+} are subject to oxidization, both abiotically by oxygen and nitrate, as well as by microbial enzyme-mediated reactions [17]. The abiotic and biotic conversion of Fe^{2+} to Fe^{3+} in solution promotes iron release from the solid. In addition, a direct biotic mechanism also exists – in this case the oxidation of reduced metals is enzymatically catalyzed at the microbe–glass interface. In-situ oxidation of these metals affects their chemical bonding within the solid, thereby favoring their release and, thus, the overall dissolution of the glass. Moreover, oxidation of Fe and Mn results in the precipitation of metal-oxyhydroxides (e.g. FeOOH), which ubiquitously occur in association with basaltic ocean crust. Other prokaryotic microorganisms then use these same phases to reduce oxidized metals.

In general, biomediated redox reactions not only satisfy the energy needs of microbes, thereby allowing them to survive and reproduce, but they also speed up these reactions compared to their abiotic counterparts. The electrons liberated by the oxidation of these elements serve to reduce CO_2 , producing elemental C. The importance of microbial C fixation in deep sea floor basalts is supported by biomass calculations, which indicate that microorganisms can fix up to 5×10^{11} g of C per year, based on the assumption that the oxidation of Fe and S in the ocean crust is entirely due to microorganisms [27]. This result thus emphasizes the importance of basalt–microbe reactions with respect to the terrestrial carbon cycle.

Other types of interactions mediated by microorganisms also play a potential role in the chemical alteration

of basalt. Extracellular polymeric substances (EPS), which are mainly composed of polysaccharides and proteins, encapsulate bacteria and Archaea and allow them to adhere to inorganic substrate (rock) surfaces. They contain carboxylic acid groups that can potentially increase chemical alteration by lowering the pH at the microbe–substrate interface. In addition, polysaccharides form ligand–metal complexes in solution, which can also increase dissolution rates [16].

Microorganisms also produce (via enzymatic reactions) and secrete a variety of chemical compounds that can have a direct effect on basalt glass alteration. Chemical ligands are one such group of compounds. These ions or molecules, which form coordinated complexes with a central metal atom, bond with certain surface atoms of the solid substrate, thereby disrupting their chemical linkages and facilitating release to solution. There is an apparent positive correlation between the microbial production of organic ligands and the release rate of Si, Al, and Fe [16] from silicates. In addition to this effect, ligand complexes in solution serve to shift the solution saturation state away from chemical equilibrium, thereby increasing metal release rates from solids. Iron-specific ligands called siderophores form very strong Fe^{3+} -chelating compounds. They can bond to surface iron sites and catalyze their release to solution [15], thereby making Fe^{+3} available for eventual metabolic reactions by organisms. Enzymatic reactions also produce organic acids, which are passively or actively excreted by microbes and can also directly enhance glass dissolution. This effect is particularly effective in crevasses and pore spaces inhabited by microbes, where very low pH values have been measured, thereby theoretically increasing dissolution rates by factors of 10–1000 (e.g. pH 3.4 in pore space vs. 7.0 in bulk solution, [28]). Aside from secreted acids, dissolved microbial metabolic products are also known to be acidic in nature, and can therefore also enhance dissolution rates.

5 Biotic Corrosion Models

A generalized model of a biologically mediated corrosion processes is shown in Figure 1 [13]. The formation of granules and elongated tubes results from localized congruent dissolution by endolithic microbes that produce complexing agents, enzymes, siderophores, and acidic pH fluids. The pH in localized microenvironments is thought to be lower than in the surrounding seawater [22], and the dissolution process is assumed to be congruent, as apparently deduced from the lack of a palagonite gel. The principal alteration products are insoluble and organic matter deposited on the granule and tunnel walls,

Figure 1 After the onset of colonization (panel A), biotic glass corrosion model results in granular textures (panel B) or tubular tunnels (panel C). The microbes mediate localized congruent dissolution, resulting in insoluble residual and organic matter, secondary authigenic minerals, but no palagonite. Source: Adapted from figure 14, [13].

whereas authigenic mineral phases precipitate on surfaces exposed to seawater. The tunneling action of the filamentous extension of the microbe (Figure 1c), similar to mycelium of fungi, is due to the secretion of acids and complexing agents at the tips of individual filaments. Dissolved nutrients and metabolic (waste) products are transported away from the dissolution front within the filaments themselves. Although the presence or absence of palagonite at the interface with the pristine glass (Figure 1) cannot be evaluated, this generalized model based on congruent glass alteration concurs with the CIDR model.

In the same study, alteration localized at cracks was also investigated [13]. As revealed by μm -scale elemental mapping by electron probe microanalysis, the edges of cracks from which granules originated exhibit a depletion of P, Ca, and Mg, suggesting the formation of a cation-depleted palagonite layer at the interface with the pristine glass. Mapping of tubular structures emanating from a

crack and penetrating into pristine glass was also done with synchrotron-based X-ray spectroscopy. Overall, these data point to cation loss from the glass and enrichment of other cations in regions occupied by the putative microbes. Owing to the μm -spatial resolution of these analyses, a more precise evaluation of the corrosion process is not possible.

Granular and tubular structures of assumed microbial origin have been examined at relatively high spatial resolution with TEM techniques, which include energy dispersive X-ray spectroscopy (EDX) and selected area electron diffraction (SAED). In a 6 Ma-old glass retrieved from east Pacific crust (Figure 2), spherical and vermicular structures extend into the fresh glass and are typically composed of 100–300 nm-wide altered glass rinds depleted in Mg, Mn, Fe, Ca, and Na, and enriched in Si, Al, Ti, and K [29]. The granular texture likely resulted from microbe-enhanced dissolution of the glass, leaving behind open tubular structures.

Figure 2 Putative microbial alteration of glass. (a) TEM image of glass and a spherical alteration structure composed of palagonite rim and phyllosilicate core. (b) HRTEM image of palagonite–phyllosilicate interface. *Source:* Adapted from figure 2, [29].

Continued incongruent dissolution of the glass led to precipitation of phyllosilicates (primarily smectite) in the open tubes, or alternatively, the smectite could have formed by in-situ replacement of the altered glass. As for the mechanisms involved, an incongruent dissolution process was suggested to yield palagonite, although the structural interfaces of palagonite with both the glass and phyllosilicate appear to be relatively sharp (Figure 2). In reality, these interfaces might have been even sharper had higher resolution imaging been achieved, thus making it possible to speculate on an interfacial reprecipitation process (CIDR). In any case, the resemblance of the spherical dissolution features attributed to biologically mediated alteration in Figure 2 with the abiotic formation of the spherical palagonite in Figure 5 is remarkable.

Other insights are possible from a study of tubules in four basalt glass samples with different provenances and ages, using various high-resolution TEM techniques [30]. With structures similar to those in Figure 2, images show the presence of fresh glass, a 20–50 nm-thick palagonite layer, and a core region containing phyllosilicates. The palagonite is depleted in Ca, Fe, Mg, K, and Mn, but enriched in Si and O, and has very sharp structural and chemical boundaries with the fresh glass and phyllosilicates at the internal and external interfaces, respectively. Without supporting or repudiating a biological origin of the palagonite present in the tubules, the authors suggested that the palagonite developed by incongruent dissolution and preferential cation leaching, followed by precipitation of phyllosilicates from a saturated solution, or by in-situ transformation of unstable palagonite [30]. Notwithstanding their interpretation, the measured Si-enrichment in the palagonite and the sharp chemical and structural interfaces agree far better with the CIDR mechanism, which would imply that the palagonite layer formed as an interfacial reprecipitate.

In another detailed study, basalt tubules investigated at the μm-scale with three synchrotron X-ray methods revealed depletion in Fe^{2+} , Ca^{2+} , and Mn^{2+} ; enrichment in Ti and Cu; and oxidation of residual iron to Fe^{3+} [31]. The tubule mineralogy is dominated by Fe^{3+} -silicates from the smectite group of clays. Whereas the biogenicity of the tubular structures remained an open question, the mechanism leading to their formation could not be unambiguously elucidated because of the insufficient spatial resolution of the analyses.

Alternatively, congruent element release and palagonite formation (Figure 3) were surmised during the chemical weathering of basalt glasses, presumably by microorganisms [32]. The palagonite occupying the tubular structures is composed primarily of insoluble Fe and Ti phases, and is separated from the glass by a gap (up to 5 μm) attributed to the pronounced loss of Si to the fluid. The physical gap [33–35] supports a CIDR process, and not preferential cation leaching. Interestingly, micrographs at the micron-scale show that the outer edges of the glass, as well as plagioclase phenocrysts, are characterized by 1 μm-thick light colored bands with distinct boundaries running parallel to the edges. These bands may in fact represent successive dissolution–reprecipitation events, but this idea would require additional work using analytical techniques with nm to sub-nm-scale resolution.

To determine the role of microorganisms in the low-temperature alteration of a 122 Ma seafloor basaltic glass, tubular and vermicular micro-channels were investigated at the nm-scale by a combination of analytical techniques, such as FIB-TEM and scanning transmission X-ray microscopy (SXTM) [36]. The micro-channels cutting through the fresh glass have 30 nm-wide Si-rich rims,

followed by palagonite with partially oxidized Fe, as well as organic carbon associated with nm-sized carbonate grains. The formation of the silica rims was attributed to incongruent dissolution and preferential cation leaching of the glass (see Figures 1–3, Chapter 5.12), which preceded the formation of the palagonite. However, two notable indices favor the CIDR mechanism: (i) the silica-rich rims have very sharp interfaces with the basalt glass and palagonite; (ii) there are abrupt, step-like changes in Si concentration between the glass and the Si-rich rim (see Figures 7 and 8, Chapter 5.12).

6 Abiotic Corrosion Models

The first step in abiotic corrosion has been stated to be hydration and chemical exchange with seawater, leading to the formation of a palagonite gel by interdiffusion of preferentially leached glass cations with chemical species from seawater, including H₃O⁺ [13]. Further alteration leads to precipitation of clays, zeolites, and iron oxyhydroxides on the palagonite gel (Figure 4). This scenario fits the interdiffusion leached-layer mechanism if the interdiffusive zone and gel are considered as the palagonite (Figures 1–3, Chapter 5.12). From high-resolution TEM images [37], the formation of palagonite was described in similar terms: incongruent glass dissolution in fracture domains leading to leached layers several tens of nm in thickness. Eventually, the Al- and Si-enriched leached layers are transformed in situ to smectite. The overall palagonitization process is characterized by a loss of Fe, Mg, and Ca, and a gain in Al, with Si enrichment being strictly restricted to the leached layer.

In a striking example of a glass alteration sequence (Figure 5a), the structural and compositional interfaces between a palagonite rind and glass are very sharp [38]. In addition, the palagonite appears to have several concentric layers delimited by sharp boundaries. A distinct

phyllosilicate layer formed at the outer palagonite interface during continued alteration. Palagonitization was associated with the creation of significant secondary porosity, and was therefore thought to involve a non-isovolumetric process – a key characteristic of CIDR [39]. Although the intrinsic mechanism of alteration

Figure 5 Alteration of sideromelane (basaltic glass) by seawater. (a) SEM image: palagonite forms by dissolution of glass at sharp reactive interface (6) – note also sharp concentric banding within palagonite (thin black arrows). (b) Chemical profiles from vesicle edge to palagonite–glass interface (1–6 arrow). Mg enrichment is a signature of seawater. Source: Adapted from figure 12, [38].

and palagonite formation was not specifically addressed, the sharpness of the glass–palagonite interface and the sharply delimited concentric palagonite layers also support the CIDR process (Figure 6, Chapter 5.12). The chemical profiles in Figure 5b cannot, however, be used to discriminate between the leached-layer and CIDR models because of their low spatial resolution.

In another model [10], the first step in volcanic glass corrosion is the formation of a yellowish-brown

amorphous gel (palagonite) rind that armors the fresh glass. The gel forms from the congruent dissolution of the glass and contemporaneous precipitation of a gel depleted in Si, Al, Mg, Ca, Na, and K, enriched in H₂O, and “passively” enriched in Ti and Fe. At the μm-scale, the sharp and distinct physical interface separating the glass from the palagonite (Figure 6) again concurs with key features of the CIDR mechanism, namely a sharp interface, congruent release of glass cations, and coupled

Figure 6 Corrosion of glass and formation of palagonite by dissolution–reprecipitation. Stage 1: fresh glass (FG) congruently dissolves with simultaneous reprecipitation of palagonite (P). Palagonite continuously forms at the expense of glass. Stage 2: palagonite transforms in situ to smectite (AGS I, AGS II). Secondary authigenic minerals may also form. *Source:* Adapted from figure 15, [10].

reprecipitation. Because the first-formed palagonite gel is unstable, further reaction with the surrounding fluid (seawater) results in the crystallization of smectite clays at the expense of the palagonite at its external surface (stage AGS I – Figure 6). Further alteration causes most of the remaining palagonite to be converted to smectite (stage AGS II) and other authigenic minerals.

The effect of glass composition was illustrated in a study [8] of the alteration of interstitial glasses of various ages, composed mainly of SiO_2 and Al_2O_3 , which produced an Mg-rich smectite clay called saponite. The 10 Å-lattice fringes of saponite observed by TEM in nm-proximity to the unaltered glass supports direct formation from the glass without a palagonite precursor phase, but whether there was a very thin intermediate gel-like phase between the glass and saponite is not known. If it did form at the expense of the glass via a solution-mediated transformation, then this process can be considered within the framework of the CIDR mechanism. However, saponite precipitation from an oversaturated bulk solution cannot be excluded.

In a completely different view concerning both abiotic and biotic corrosion [40], granular palagonite textures and tubular etch tunnels in basalt glass were linked to damage to the glass structure caused by radioactive decay of U and Th, which are trace elements in all basalts. Selective dissolution of alpha-recoil and fission tracks yields abiotic granular and tubular structures mimicking biotic alteration textures (Figure 7). As for the filaments that are frequently observed and often considered to be of biological origin, the authors argued that they might in fact be long tubular strands of imogolite, a secondary aluminum silicate clay mineral $[\text{Al}_2\text{SiO}_3(\text{OH})_4]$ [40]. On the other hand, certain types of complex tubular textures, such as micro-tunnels with spiral/helical, annulated, dendritic, and palmate structures cannot be attributed to dissolution of radiation-damaged glass [40], or any other known abiotic corrosion process. Nonetheless, the lack of nm-scale chemical and structural data in this study precludes identifying any specific alteration mechanism.

7 The Abiotic vs. Biotic Alteration Debate

The possibility that seafloor basalts have preserved traces of biotic chemical weathering up to 3.5 billion years old [13] is one of the most central issues concerning Earth's early evolution. This explains why studies of seawater alteration of basalt glasses have been largely devoted to the thorny issue of differentiating abiotic and biotic alteration signatures. Chemical and structural criteria have been proposed for the assignment of tubular structures to bioalteration [13]. The principal argument in favor of biogenicity is that granular, and, in particular, complex tubular structures are not likely to form from an abiotic dissolution process. In addition, chemical analyses of tubes in basalt glasses have evidenced DNA fragments and enrichment in certain elements (C, N, and P) [13]. Organisms had thus been present therein at one point in time, although there is no absolute proof that they created the actual tubes. In fact, it has been impossible to link directly specific microorganisms to granular and tubular textures found in altered glasses (e.g. [23]).

Even the use of very advanced nanometer-scale analytical techniques did not allow for the discrimination between an abiotic or biotic origin for micro-channels in ancient seafloor basalt glasses [36]. The debate is particularly tenuous with respect to putative biological tubular structures in glasses dating to the Archean (4–2.5 billion years) [13, 23, 36, 41, 42]. For example, a recent study [23] shows a convincingly close physical resemblance between tubular structures found in a fresh glass from the Troodos ophiolite and tubular structures replaced by titanite $[\text{CaTiSiO}_5]$ from the Barberton greenstone belt (metamorphosed basalts with ages up to 3.6 Ga). On the other hand, a detailed study of titanite-bearing microtubes in an Archean volcanic ash did not yield solid evidence in favor of bioalteration when examined with submicrometer-resolution methods [41].

Figure 7 Abiotic corrosion of basaltic glass. Palagonite rim initially forms in a seawater-filled fracture, followed by preferential dissolution of radiation-damaged sites, resulting in complex microtextures strongly resembling biotic textures. Last panel: granular palagonite alpha-recoil track alteration (GP(ART)); alpha-recoil track etch tunnels (ARTETs); fission track etch tunnels (FTETs). *Source:* Adapted from figure 18, [40].

Adding to the debate, microbial culture studies provide evidence that bacteria growing on basalt glasses do play a direct role in the release of Si, Fe, and Mn to solution [43]; however, their overall degree of contribution to dissolution still remains largely unknown [15]. Notwithstanding, globular and tubular structures have never been replicated in the laboratory [31], but this may be simply due to the extreme slowness of biotic alteration.

8 Which Mechanism Controls Basalt Glass Corrosion?

The studies concerning biotic and abiotic alteration of basalt glasses present for the most part μm -scale cross-sectional images and chemical analyses of pristine basalt glass, palagonite, secondary authigenic minerals, and putative microbial remnants. Can these results be used to support one or the other alteration mechanism?

No single mechanism could be deduced from the abiotic group. In some studies a corrosion mechanism was not proposed [38, 40], or an incongruent dissolution/leached-layer mechanism [13, 37] was simply assumed. Others argued for palagonite formation through coupled congruent dissolution–precipitation (i.e. CIDR) [10], or direct transformation of glass into sapponite [8]. For the latter, one cannot rule out precipitation of sapponite from a saturated solution, or alternatively, transformation of a precursor palagonite into sapponite. Interestingly, hallmarks of CIDR have been reported in the abiotic group, such as Al- and Si-enriched secondary layers [37], or secondary porosity and/or sharp interfaces [8, 10, 38].

In the biotic group, the granular and tubular structures are not associated with unequivocal evidence in favor of one or the other corrosion mechanism. Whereas a specific mechanism could not be confirmed in one case [31], four others argued for initial corrosion by preferential cation release [13, 29, 30, 36]. Another investigation

[32], as well as the general model in [13], proposed congruent dissolution followed by precipitation. As with the abiotic studies, studies actually did show sharp interfaces and Si-rich glass corrosion rims that fit best with the CIDR model [29, 30, 32, 36].

Both the abiotic and the biotic corrosion studies considered the formation of secondary authigenic crystalline phases, in particular phyllosilicate minerals, in terms of two processes, namely, precipitation from a saturated solution and in-situ transformation of palagonite or fresh glass. In all cases, the authigenic minerals that occupy granular and tubular structures have very sharp interfaces with palagonite or glass, e.g. [29, 38]. Sharp chemical and structural interfaces are strong evidence for the CIDR mechanism (Chapter 5.12, see also [35, 44, 45]).

9 Perspectives

The precise molecular-scale mechanism controlling the abiotic and biotic alteration of basaltic glasses in seawater remains an open question. To date, most seawater–basalt glass studies have used analytical approaches with spatial resolutions in the μm to sub- μm -range, making it problematical to define the operative mechanism controlling alteration. Only a few studies, e.g. [30, 36], have published chemical and structural data at the nm-scale. Further progress in this field will thus certainly depend upon detailed investigations of glass alteration using more advanced, high-resolution analytical techniques. As described in Chapter 5.12, how glass samples are prepared and which analytical techniques are used is of critical importance for deciphering the molecular-scale mechanism of alteration. These tools will ultimately permit identifying the actual glass corrosion mechanism, and hopefully, may even help in the debate on deciphering abiotic and biotic alteration signatures. Of course, chemical, isotope, and structural data obtained at the nanometer scale should also be used in a complementary manner with large-scale mass balance calculations, and perhaps even be integrated into thermodynamic–kinetic models to be used as predictive tools for understanding basalt glass–seawater interactions over long periods.

7.4

Metallurgical Slags

Kenneth C. Mills

Department of Materials, Imperial College, London, UK

1 Introduction

Metals have been a major factor in the development of human societies. This importance is illustrated by the way in which this evolution has been charted in terms of the celebrated Bronze, Iron, and Steel Ages. But the key role long played by molten silicates termed *slags* in the success of metallurgical processing is in contrast not so well known. As passed from one generation of steelmakers to the next, however, the old adage “Look after the slag and the metal will look after itself” testifies to the fundamental importance of this slag phase. In steelmaking, slags are, for instance, involved in all processes (iron making → steelmaking → primary refining → secondary refining → casting). The current steel production of about 1.6 billion tons per year thus involves more than 300 million tons of slag [1], which represents about three times the yearly glass production. And even though the figures are smaller, slags also participate in the processing of other metals such as aluminum (58 million tons p.a), silicon (8), or copper (5.5).

Metals mostly naturally occur under the oxidizing conditions of the Earth’s surface as oxides, sulfides, etc., so energy is needed to break the M–O and M–S bonds in order to reduce the oxidized forms and produce metals. This reduction can be achieved in different ways. Iron oxides are, for instance, reduced above 700 °C by CO(g) (originating in the combustion of coke or coal) in the blast furnace where 1 ton of pig iron and 0.25 ton of slag are produced by reaction of 1.6 tons of FeO_x ore with 0.45 ton of coke and 0.2 ton of CaCO₃. This *pig iron* contains about 4 wt % (or nearly 20 at. %) carbon; the C atoms sit in the interstices of the Fe matrix and

impart mechanical strength but provide little ductility (needed to obtain parts of desired shapes by rolling, extrusion, die forming, forging, etc.). Thus, steelmaking primarily consists of (i) removing carbon, which one achieves by reacting the C with O₂ flowing from a submerged lance; (ii) minimizing elements that harm the mechanical properties of steels; (iii) and minimizing *inclusions* (i.e. solid oxide particles such as Al₂O₃ or entrapped slags formed in the process), which reduce the mechanical strength of the steel.

Other reducing agents are hydrogen (from natural or water gas) or more reactive metals, for instance, Al in the aluminothermic reduction of Cr and Mn oxides. For the extremely stable aluminum oxide or hydroxide ores, electrolysis requires dissolution in an electrolyte that melts at a temperature much lower than the fusion temperature of Al₂O₃ (2050 °C). In the Hall–Héroult process, this is achieved with a cryolite [Na₃AlF₆] electrolyte to which about 4–6 wt % CaF₂ and 10–12 wt % AlF₃ are added to lower the melting point of cryolite from 1011 to 920–970 °C. Electrolysis then produces Al at the cathode and O₂ at the anode, the latter reacting with the consumable graphite electrodes to form CO(g); this provides much of the required energy for metal production. New Al₂O₃ is then added periodically to the electrolyte to keep its concentration close to the solubility limit of about 6 wt %.

Copper occurs principally in nature as mattes (i.e. sulfides such as chalcopyrite, CuFeS₂). The matte is processed in two stages: (i) oxidation of FeS according to the reaction FeS + 1.5 O₂ (from oxygen-enriched air) = FeO + SO₂(g) and then reaction of FeO with SiO₂ to form a fayalite slag (2 FeO·SiO₂), which is readily separated from the denser Cu₂S, and (ii) oxidation of Cu₂S to form blister copper, Cu₂S + O₂ = 2 Cu + SO₂(g).

Slags are critical to the success of metallurgical processing because they carry out many important tasks for

Reviewers: Z. Li, WMG, University of Warwick, Coventry, England, UK
S. Seetharaman, Materials Science and Engineering, Royal Institute of Technology, Stockholm, Sweden

which their physical properties must be finely tuned (Table 1). As metallurgical processes may differ widely, some of the functions of the slag are common to most of them, while others tend to be specific for a given one. The common functions include the following (key physical property of the slag indicated in brackets):

- To form a liquid slag layer that seals the metal surface from the atmosphere (liquidus temperature, T_{liq}).
- To provide thermal insulation and prevent the surface of the liquid metal from freezing (thermal conductivity, k , and porosity).
- To aid the removal of oxide and nitride inclusions from the metal (density, ρ).
- To remove elements like S, P, As, and B, which have deleterious effects on metal properties (S capacity, P capacity, etc. and T_{liq}).
- To ensure optimum heating when used in electric arc furnaces and to minimize energy costs (electrical resistivity, R).

This demand for slag properties is set to increase dramatically since these are needed as input data for mathematical models of metallurgical processes, which are now capable of identifying the mechanisms responsible for operational problems and product defects. The purpose of this chapter is to review these various issues in terms of slag properties and show how they can be now predicted as a function of the relevant parameters, of which composition is the most important. Although liquid slags are the principal focus in most metallurgical processes, the properties of solid slags are also critical in the continuous casting (CC) of steel and some other processes.

2 Basic Constraints: A Summary

2.1 Fast Kinetics

High production rates are essential in modern metal making, so any reactions involved in the process must be fast. One way of promoting fast kinetics is to maximize the interfacial area between metal and slag. In practice, one achieves this goal by creating emulsions of metal in the slag, which are promoted by the formation of slag foams; these emulsions are formed by the metal flow turbulence induced by submerged oxygen lances or by the use of high casting speeds in the case of CC (Figure 1). For example, in the basic oxygen steelmaking (BOS) process, 300 tons of molten steel are emulsified in the slag foam in less than 30 minutes. The interfacial (area/mass [or volume]) ratio of the metal drop is the key factor, which is proportional to the reciprocal of the droplet radius r . Foam stability is also important and is promoted by low values of slag surface tension (γ), high viscosity (η), and high liquidus temperature (T_{liq}) since solid particles retard slag drainage rates and therefore stabilize the foam.

2.2 Slag/Metal Entrapment

One consequence of producing metal emulsions in the slag is the loss of metal yield. This problem is especially important in the production of precious metals and of copper. Similarly, in the continuous casting (CC) of steel, turbulent metal flow causes entrainment of slag droplets in the metal. Slag inclusions reduce the mechanical strength of the steel. Entrapment can occur by a variety of mechanisms, for instance, by that shown in Figure 2

Table 1 The required functions of the slag and important physical properties and approximate composition: A = Al_2O_3 ; C = CaO; F = FeO; FI = CaF_2 ; M = MgO; Mn = MnO; N = Na_2O ; and S = SiO_2 .

Process ^a	Process aim	Slag function (slag properties)	Slag composition
Fe-BF	$\text{FeO} + \text{C} = \text{Fe} + \text{CO}$	Minimize impurities	CSAM; (C/S) = 1.1

from the formation of vortices in the slag [2]. One can minimize it by using slags with high values of both viscosity and slag/metal interfacial tension (γ_{ms}). Metal entrainment in the slag can also be reduced with low values of slag density (to promote removal) and high values of γ_{ms} .

2.3 Refractory Protection

A serious problem in metal production is refractory erosion, especially when turbulent metal flow is involved, to the point that some processes have been abandoned because erosion rates were too high. One technique used to extend refractory life is to create *freeze linings*; these are formed by water cooling of the refractory and covering of the hot face with a consumable layer of solidified slag so that the freeze lining protects the refractory from erosion. For example, at the end of the BOS process, the lance used in the oxygen blow is lowered, and liquid slag is splashed to cover the refractory walls (this is referred to as *slag splashing*). The resulting slag coating protects the refractory from the turbulent metal and slag flows in the next heat. Refractory lives of more than 50 000 heats have been achieved in this way. However, for successful splashing, it is important that the slag have a FeO content of ca. 13 wt % (for good adhesion to the refractory) and contains more than 8 wt % MgO to ensure the formation of a high melting phase leading to a low consumption rate. Freeze linings are consumable, however, and do give rise to slag inclusions in the metal.

Figure 2 Sketch of slag/metal entrapment. (a) Metal flow pattern in the mold. (b) Necking and detachment mechanism for the entrapment of slag in metal. (c) Location of slag inclusions on slab arising from this mechanism [2].

2.4 Electrical Conduction

Electric arc furnaces are used in smelting and refining operations. Because the heat for the process is usually generated from the arc struck in the slag phase, the composition of the latter is selected on the basis of its electrical resistivity (R , since the energy supplied is given by I^2R). This property is a key factor in this context. In electric arc furnace steelmaking, foaming slags are used to improve heat transfer from the arcs to the metal phase.

2.5 Heat Transfer

In continuous casting, molten steel flows from a submerged entry nozzle (SEN) into the mold (Figure 2) and freezes against the water-cooled copper wall to form

a shell [3]. Two precautions are taken to prevent the shell from sticking to the mold, namely, (i) the mold is oscillated vertically, and (ii) a casting powder is added to the top of the mold where it forms a liquid slag pool from which slag infiltrates between the shell and the copper to form a film (Figure 2). This film consists of two layers, one solid ($d_s = 1\text{--}2$ mm thick) and the other liquid ($d_l = \text{ca. } 0.1$ mm thick). Serious defects in the cast steel occur if the heat transfer from the shell is not optimal. The principal factors affecting horizontal heat transfer are (i) the thickness of the slag film, which is controlled by the solidification (or break) temperature, T_{br} , of the slag, and (ii) the fraction of crystalline phase in the film, f_{crys} , which also contains a glassy phase, because the conduction of heat by radiation (k_R) decreases as f_{crys} increases [3].

2.6 Lubrication

The friction force (F) exerted on the steel shell formed in continuous casting (Figure 2b) is given by $F = A(V_m - V_c)\eta/d_l$ where A is the surface area of the mold and V_m and V_c are the velocities of mold and shell, respectively. Thus friction forces increase with increasing viscosity (η) and decreasing liquid film thickness (d_l).

3 From Composition to Reactivity

3.1 Compositions of Metallurgical Slags and Fluxes

Because of the specific needs of metal production processes, slags cover a wide range of compositions (Figure 3). These are also summarized in Table 2 where the principal functions and important properties of slags

used in iron making and steelmaking and copper, aluminum, and silicon production are also listed. Although these compositions are related to those of glasses and coal ashes (Chapter 9.9), as shown by the pseudo-ternary diagram of Figure 3, they are distinctly different in view of their lower SiO_2 and Al_2O_3 contents. Slags are low-viscosity, highly basic melts, which is not at all accidental since the former property is beneficial for rapid processing and the latter is required to remove sulfur and phosphorus whose effects on metal properties are deleterious: although the former improves machinability and the latter slightly improves strength and hardness, both reduce the ductility and impact strength and weldability of cast

Figure 3 Composition ranges for metallurgical slags shown as a ternary diagram of mole fractions of SiO_2 , Al_2O_3 , and M_xO^* , where $X_{\text{M}_x\text{O}^*} = X_{\text{M}_x\text{O}} - X_{\text{Al}_2\text{O}_3} = \Sigma(X_{\text{CaO}} + X_{\text{MgO}} + X_{\text{FeO}} + X_{\text{MnO}} + X_{\text{Na}_2\text{O}} - X_{\text{Al}_2\text{O}_3})$, i.e. network-modifying oxides after charge balancing of Al_2O_3 ; Min = minerals; BF = blast furnace; Cu = copper making; Fe/Cr and Fe/Mn = ferroalloys; SS = secondary (refining) steelmaking slags.

Table 2 Typical compositions for slags from different processes.

	CaO	SiO ₂	Al ₂ O ₃	MgO	FeO _x	MnO	Na ₂ O ^a	CaF ₂	Others
BF slag	42	34	13.5	7.5	0.5	0.3	1		S, 1

iron. The viscosity of slags is also lowered by the fluxes incorporated to reduce the liquidus temperatures. The most common are CaF_2 , B_2O_3 , and Na_2O . Boron is considered a harmful impurity in both steel and silicon, whereas CaF_2 levels have been reduced in recent years in metallurgical slags to meet environmental concerns.

3.2 Reactivity of Slags

Ranging from the *docile* to the *hostile*, the reactivity is a key factor in the selection of a slag composition. In this respect, the ionic nature of slags is a fundamental feature because reaction with the metal involves the transfer of electrons (e.g. $2\text{Al}_m + 3\text{Fe}_{\text{sl}}^{2+} = 2\text{Al}_{\text{sl}}^{3+} + 6\text{Fe}_m$, where the subscripts m and sl denote the metal and slag phases, respectively). The reactivities of slag components can be ranked by use of Ellingham diagrams (Figure 4) in terms of the chemical stability of component oxides (Chapter 5.6). Stable oxides with highly negative Gibbs free energies (ΔG) are located toward the bottom of the figure (e.g. CaO), whereas less stable ones (e.g. FeO) are sited near its top. Reactive metals (e.g. Al in steel) will take the oxygen away from less stable oxides (like FeO) located above them in the figure. Thus slags containing high contents of FeO and Cu_2O tend to be unstable and very reactive.

The reactivity also increases with temperature, so slags used in metal processing tend to be more reactive when melting at higher temperatures. In laboratory experiments it is customary to contain oxides (i.e. slags) in metals and vice versa. In industrial processes, the vessel is usually lined with refractory oxides (i.e. stable oxides located near the bottom of Figure 2) since (i) these are less

reactive and (ii) these have high melting temperatures as a result of their strong M—O bonds.

Refractory erosion is a serious problem for the metallurgical industry as slags readily dissolve oxides since they are themselves oxides. The erosion rate is particularly severe around the metal/slag interface, which is known as *slag line erosion*. Here, erosion is caused by the formation of vortices in the meniscus region of the slag from dissolution of refractory oxides, which creates a surface tension gradient and results in a Marangoni surface flow from low to high surface tension [4].

Modern refractories consist of a mixture of oxides and carbon because the carbon particles alleviate the thermal stresses produced. A different mechanism causes their erosion [4]. Metals are wetting carbon but not oxides, whereas slags are wetting oxides and not metals. When the refractory surface consists mostly of carbon particles, the metal advances, covers them, and subsequently dissolves them. As a result, the surface mainly consists of oxide particles, so the metal recedes, and the slag covers the oxide particles and dissolves them until the surface is primarily made up of carbon particles. The cycle then starts over again.

The main driving force for dissolution is the concentration gradient ($C_{\text{sat}} - C_{\text{proc}}$) where the subscripts refer to the concentrations at the saturated limit and actual level in the process. In some processes, one minimizes refractory erosion by increasing C_{proc} close to the C_{sat} level.

4 Slag Properties

4.1 General Features

As already emphasized, the ability of the slag to perform its required functions in metal processing relies heavily on its properties. In Table 3, their values are, in turn, closely related to the structure of the slag, which tends itself to be dominated by its degree of polymerization at high temperatures. With respect to the properties considered, however, the strength of this relation is in the hierarchy: viscosity (η) > diffusion coefficient (D) $\approx$ electrical conductivity (κ) > thermal conductivity (k) > thermal expansion coefficient (α) > density (ρ) > heat capacity (C_p). The two other principal factors affecting both structure [5–7] and physical properties [8, 9] are the nature of the cations and temperature.

4.2 Polymerization of the Slag

That the degree of polymerization is an important parameter is clearly illustrated by the increases of viscosity with the size of the elementary structural units of the melt (Figure 5) and, especially, by the dramatic increase

Figure 4 Ellingham diagram: Gibbs free energy of the reactions $\text{M} + \text{O}_2 = \text{M}_x\text{O}_2$ for various component oxides as a function of temperature.

Table 3 Comparison of approximate property values at specified temperatures for various metallurgical slags with those reported for molten minerals and coal ashes; □ = estimated value.

Property (Q)	BOS (<0)	BF (2)	CC(1.8–3.2)	Basalt (3.1)	Rhyolite (4)	Coal ash (4)
$\eta_{1900\text{ K}}$ (dPa s)	0.2–1	1–3	0.1–5	4–7	100–300	100–200
$\kappa_{1900\text{ K}}$	5	0.4–0.8		0.2–0.6	0.3–0.6	0.01–0.02

$k_{1000\text{ K}}$	—	1.55	1.65–2	1.8	1.7	1.8
$\rho_{1900\text{ K}}$	2050	2720	2500	2700	2400	2550

**Figure 5** Values of $\ln$ viscosity (dPa s) at 1900 K for various silicates and aluminosilicates as a function of the polymerization parameter Q ; individual symbols refer to different cations; structures from left (i) single tetrahedra, (ii) double tetrahedra, (iii) three-membered rings, (iv) single chains, (v) double chains, (vi) sheets, and 3-D structures [9].

observed when 3-D structures begin to form. Several parameters have been used to characterize the polymerization of slags. Some of them are indirect measures, like the *basicity* (expressed as the CaO/SiO_2 ratio) and the *optical basicity* (Chapter 5.7), which characterizes the electron donor power. Others are defined in terms of basic structural units, namely, bridging (BO, denoted by O°), nonbridging (NBO, O^-), and free (FO, O^{2-}) oxygens, along with tetrahedrally coordinated cations (T), and yet another is very simply the *viscosity*.

The degree of polymerization is often defined in terms of two simple composition parameters. As discussed in more detail in Chapter 2.6, the first is

$$\frac{\text{NBO}}{T} = \frac{\sum 2(X_{\text{MO}} + X_{\text{M}_2\text{O}} - X_{\text{Al}_2\text{O}_3})}{(X_{\text{SiO}_2} + 2X_{\text{Al}_2\text{O}_3})}, \quad (1)$$

where X denotes a mole fraction. As to the second parameter, it is simply

$$Q = 4 - \frac{\text{NBO}}{T}. \quad (2)$$

Both parameters are modified basicities providing measures of depolymerization and polymerization, respectively. Alternatively, the numbers of BOs, NBOs, and FOs have also been used, or those of the Q^n species derived from spectroscopic experiments (Chapters 2.2 and 2.4). When relating NBO/T and Q to structure and properties, however, the big problem is that these parameters do not differentiate between different cations. Optical basicity (Λ) was introduced as a remedy (Chapter 5.7), but it predicts wrong trends for the viscosity ($\eta_{\text{M}_2\text{O}-\text{SiO}_2}$, in hierarchy $\text{K} > \text{Na} > \text{Li}$ but Λ gives a reverse trend). Until recently, a cell model [10] was required to calculate the numbers of BOs, NBOs, and FOs, but a new model to determine these parameters has become available and offers exciting opportunities [11].

In spite of its shortcomings, the parameter Q has been adopted here as a convenient way to represent the degree of polymerization (Figure 6). It should be noted that most metallurgical slags have Q values ranging from 0 to 2, whereas glasses, minerals, and coal ashes generally have Q values higher than 3. One consequence is that a property such as viscosity shows much more variation with structure, as represented by Q , for glasses, minerals, and magmas than for metallurgical slags (Figure 5).

4.3 Effect of Cations on Properties and Structure

The Si^{4+} cations are mostly arranged in fourfold coordination (denoted $^{(4)}\text{Si}^{4+}$). The network-modifying cations are often arranged in sixfold coordination in an octahedral array [5–7 and Chapters 2.1, 2.2, and 2.4]. However, on occasions there may be deviations in the coordination number (N_{coord}), which tends to increase with increasing cation size [6, 7]. The structure is also affected by the nature of the cations (illustrated by the scatter in viscosities plotted in Figure 5) although the effect is much smaller than that of polymerization.

The *field strength* of the cation, given as z/r^2 where z and r are the charge and radius of the ion (Chapter 2.4), is used as a measure of the effect of a cation on both

Figure 6 Effect of the polymerization parameter Q on viscosity. (a) Values of $\ln \eta_{1900 \text{ K}}$. (b) The parameters B_A . Curves, silicates; individual points, aluminosilicates. B_A curves higher for MO-SiO_2 than for $\text{M}_2\text{O-Al}_2\text{O}_3\text{-SiO}_2$ systems [12].

silicate structure and slag properties. Increasing cation field strength results in the following structural changes [6–8]:

- A wider distribution of polymeric species (Q'').
- A lower coordination number (N_{coord}), which, in turn, affects the numbers of BOs and NBOs present.
- A more compact distribution of intertetrahedral bond angles (Si–O–Si or Si–O–Al in aluminosilicates), which affects the amount of disorder present (i.e. configurational entropy).
- An increasing attraction for NBOs (e.g. $\text{Mg}^{2+} > \text{Ca}^{2+}$).
- A lower probability of charge balancing tetrahedrally coordinated Al^{3+} (Chapter 2.4), which is preferentially done by the cations with the lowest z/r^2 .

5 Transport Properties

Some physical properties vary more than others with the structure of the slag. They are discussed below in the order of decreasing dependences.

5.1 Viscosity

Viscosity is the resistance to the flow of one layer of the liquid over another (Chapter 4.1). Large silicate units make the bond exchanges involved in viscous flow more difficult, so the viscosity increases, whereas the effects of the nature of network-modifying cations are much smaller (Figure 5). In metallurgy, the Weymann equation has been used to account for the temperature dependence of viscosity:

$$\eta = A_W T \exp\left(\frac{B_W}{T}\right), \quad (3)$$

where A_W and B are constants. However, Arrhenius and Vogel–Fulcher–Tammann (VFT) equations (Chapter 4.1) are more commonly used for the stable and supercooled liquids, respectively. The former is

$$\eta = A_A \exp\left(\frac{B_A}{T}\right) = A_A \exp\left(\frac{E_\eta}{RT}\right), \quad (4)$$

where A_A is a pre-exponential term, E_η the activation energy for viscous flow, and R the gas constant. With the extra fit parameter T_o , a VFT equation is selected for the supercooled domain, for instance, in solid slag films formed in continuous casting, especially those used to cast billets:

$$\eta = A_V \exp\left[\frac{B_V}{(T - T_o)}\right]. \quad (5)$$

From plots of viscosity against the structural parameter Q (Figure 6), it appears that:

- Values of $\ln \eta_{1900 \text{ K}}$ are in the order $\text{K} > \text{Na} > \text{Li}$, i.e. $\ln \eta_{1900 \text{ K}}$ increases with increasing cation size (or decreasing field strength $[z/r^2]$), but the analogous trend is less clear-cut for MO silicates, which approximates to $\text{Mg} > \text{Ba} \approx \text{Sr} \geq \text{Ca}$.
- Both the viscosity ($\ln \eta_{1900 \text{ K}}$) and the activation energy term (B_A) are very dependent upon structure (Figure 6), in a way that can be expressed as double-exponential equations for the following systems:

$$\begin{aligned} \text{MO} + \text{M}_2\text{O} - \text{SiO}_2 : \ln \eta_{1900 \text{ K}} = & -2.16 + 0.828 \\ & \exp\left(\frac{Q}{1.794}\right) + 2.19 \times 10^{-16} \exp\left(\frac{Q}{0.1036}\right), \end{aligned} \quad (6)$$

$$\begin{aligned} \text{MO} - \text{SiO}_2 : B_\eta^* = & -795831 + 8.48 \times 10^{-6} \\ & \exp\left(\frac{Q}{0.261}\right) + 795841.4 \exp\left(\frac{Q}{211587}\right), \end{aligned} \quad (7)$$

$$M_2O - SiO_2 : B_{\eta}^* = -24.6 + 6.12 \times 10^{-13} \exp\left(\frac{Q}{0.1258}\right) + 28.5 \exp\left(\frac{Q}{7.7}\right), \quad (8)$$

where $B^* = B/1000$ and η is in dPa s [12].

- iii) Values of B_A are higher for MO than for M_2O silicates [12].
- iv) Values of $\ln \eta_{1900\text{ K}}$ and B_A for aluminosilicates are lower (for $Q > 2.8$) than for silicates (Figure 6). These departures, $\Delta \eta_{1900\text{ K}}$ and ΔB_A , increase with the ratio $[2X_{Al}/(X_{Si} + 2X_{Al})]$, a trend that may be due to weaker bonding for Al—O than for Si—O bond or to the formation of AlO_5 species (Chapter 2.4).
- v) At high Al_2O_3 contents, cations are needed to charge-balance Al^{3+} ions in tetrahedral coordination; the viscosity is at a maximum when the ratio $(X_{Al_2O_3}/X_{\Sigma X_{MO}}) \approx 1$ [7, 8], but such situations are rare in metallurgical slags.

Most slags show only a gentle increase of $\ln \eta_{1900\text{ K}}$ and activation energy term ($B_A/1000$) when Q increases from 0 to 2, whereas, with values in the 3–4 range, glasses and molten minerals display exponential increases in both parameters with increasing Q .

5.2 Electrical Conductivity and Resistivity

Transport of electricity represents the movement of charges in response to the application of an electric field. The electrical resistivity is the reciprocal of the conductivity ($R = 1/\kappa$) and is a measure of the resistance of the silicate to the transport of these charges. Electrical conduction occurs by two different mechanisms in oxide melts in general and in molten slags in particular (Chapter 4.2):

$$\kappa_{\text{total}} = \kappa_{\text{ion}} + \kappa_{\text{elec}}. \quad (9)$$

The first mechanism is *ionic conduction*, which is usually predominant and is given by

$$\kappa_{\text{ion}} = F \sum c_i z_i n_i, \quad (10)$$

where F is Faraday constant and c_i , z_i , and n_i are the concentration, charge, and mobility of ion i , respectively. The transported species are usually cations since silicate anions tend to be large and sluggish and, thus, less mobile. At high temperatures, the principal factors increasing the ionic conductivity are (i) lower degrees of polymerization (i.e. low Q), which is a measure of the resistance to the flow of cations, (ii) higher concentration of cations available for transport (NB: this concentration is $N X_{MxO}$, where N is the number available cations, whereas for $X_{Na_2O} = X_{CaO}$ there are twice as many Na^+ ions as Ca^{2+} ions), and (iii) decreasing cation sizes.

The second mechanism is *electronic conduction*, which occurs by electron hopping between M^{2+} and M^{3+} ions, where M represents a multivalent transition metal, e.g. Fe (Chapter 4.2). Both M^{2+} and M^{3+} are needed for electronic conduction and κ_{elec} is at a maximum when $X_{M2+} \approx X_{M3+}$ [13]. In slags, it is appreciable only for high concentrations of transition metal oxides (i.e. with more than 60 % FeO_x), which results in a sharp increase in the electronic transference number [13].

The silicate structure resists both viscous flow and the movement of cations when an electric field is applied. Hence, the temperature dependences of the electrical conductivity and resistivity can be expressed as Arrhenius relations at superliquidus temperatures:

$$\kappa(\Omega^{-1} \text{ cm}^{-1}) = A_{\kappa} \exp\left(\frac{-B_{\kappa}}{T}\right), \quad (11)$$

$$R(\Omega \text{ cm}) = A_R \exp\left(\frac{B_R}{T}\right). \quad (12)$$

Alternatively, a VFT-like equation has to be used for supercooled liquids:

$$R(\Omega \text{ cm}) = A_{VR} \exp\left[\frac{B_{VR}}{(T - T_o)}\right]. \quad (13)$$

Values of $\ln R_{1900\text{ K}}$ and B_R , when plotted against Q for silicates and aluminosilicates (Figure 7), indicate that:

- i) Both parameters increase with increasing polymerization.
- ii) There is a gap between $MO-SiO_2$ and M_2O-SiO_2 curves, which is assigned to the difference in the available cations (N).
- iii) The scatter around the curves is not random since both $\ln R_{1900\text{ K}}$ and B_R values increase with increasing cation size.
- iv) Values of $\ln R_{1900\text{ K}}$ for aluminosilicates are lower than for silicates.
- v) Values of the activation energy term, B_R , are higher for aluminosilicates than for silicates.

Substitution of Al^{3+} for Si^{4+} in the structure results in:

- a) Simultaneous increases in the magnitude of Q and decreases in the number of available cations (N , because cations are needed for charge balancing) causing increases in both $\ln R_{1900\text{ K}}$ and B_R .
- b) A relative decrease in the resistance to viscous flow (Figure 6), cf. that for silicates since both $\ln \eta_{1900\text{ K}}$ and $B_{A\eta}$ are reduced.

The latter effect is more important for $\ln R_{1900\text{ K}}$, whereas the effect of Q and N is dominant for B_R (Figure 7c and d).

Figure 7 Effect of the polymerization parameter Q on the electrical resistivity of silicate (points) and aluminosilicate (curves) melts. (a) and (b) $\ln R_{1900\text{ K}}$ and activation energy B_R for silicates; + = LS; x = NS; * = KS; o = CS; ▲ = MS; ◇ = SrS; * = BS; ▲ = FS; ■ = MnS; ◆ = MFS. (c) and (d) $\ln R_{1900\text{ K}}$ and B_R for aluminosilicates [14].

As shown by Figure 7a and b, values of both $\ln R_{1900\text{ K}}$ and B_R depend less on Q for metallurgical slags ($Q = 0-2$) than for molten minerals and glasses ($Q = 3-4$).

5.3 Diffusion Coefficients (D)

Diffusion is a process whereby ions or atoms move through the sample by making a series of jumps from one vacant site to another. Diffusion takes place in the direction from a region of (high $\rightarrow$ low) concentration of the diffusing species. There are several types of diffusion, namely, self, tracer, impurity, and chemical (Chapters 4.3 and 4.4).

In addition, interdiffusion occurs when two or more species are involved, e.g. a cation and a large sluggish anion (Chapter 4.4). The anion moves more slowly than the cation, which results in the formation of an electric field that retards the cation and accelerates the anion movements.

Measurements of the diffusion coefficient (D) in liquid slags are prone to uncertainty because of the difficulty of eradicating convection in experiments. The diffusion coefficient is the equivalent to the electrical conductivity and the fluidity (i.e. reciprocal of viscosity). The experimental values of $\ln D$ tend to increase with:

- Decreasing degree of polymerization (Q) of the slag since silicate species resist the movement of ions.
- Decreasing size of the diffusing species ($\ln D$ values for, $\text{Li} \approx \text{Na} > \text{K} > \text{Rb} > \text{Cs}$).
- Increasing number of cations available for diffusion (N , which is related to $[2/Z]$ where Z is the valence of the ion).
- Increasing temperature (the temperature dependence for the liquid can be expressed as an Arrhenius relation, $D \text{ (m}^2 \text{ s}^{-1}) = A_D \exp(-B_D/T)$, and by a VFT relation for the supercooled liquid, $D \text{ (m}^2 \text{ s}^{-1}) = A_D \exp[-B_D/(T - T_0)]$).

Although the $\ln D$ values for geological melts are in the hierarchy $\text{Li}^+ \approx \text{Na}^+ > \text{K}^+ > \text{Rb}^+ > \text{Cs}^+$, the effect is less marked for M^{2+} cations ($\text{Ba}^{2+} \approx \text{Sr}^{2+} > \text{Ca}^{2+} > \text{Mg}^{2+}$). It has been proposed that there are two factors affecting the diffusion process in geological melts [15], namely:

- The detachment of the diffusing ion (i.e. through the breaking of the existing M–O bond).
- Its subsequent movement through the melt.

The overall diffusion coefficient will be determined by the slower of these two steps. In the case of M^+ ions, the M–O bonds are weak (z/r^2 is low), so detachment

is relatively easy, and thus D is determined by the movement of the M^+ ions through the silicate network (hence $Li^+ \approx Na^+ > K^+ > Rb^+ > Cs^+$) [16]. However, for the M^{2+} cations, the $M-O$ bond strength (related to z/r^2) is high, so detachment of M^{2+} ions is the slow step, and, thus, diffusion will increase as z/r^2 decreases (i.e. $Ba^{2+} \approx Sr^{2+} > Ca^{2+} > Mg^{2+}$). However, the hierarchy is also affected by the degree of polymerization (i.e. Q) since the amount of free space in the melt increases with increasing Q values. Thus for high- Q melts (e.g. molten minerals), there is plenty of space, and cation detachment is the controlling factor, whereas, in lower- Q melts (e.g. metallurgical slags), there is little space, and D is determined by cation size [16]. Metallurgical slags in general have low Q values and higher concentrations of M^{2+} than of M^+ ions. Application of the above theory to slags is a little confusing since (i) a low Q would mean D increases with decreasing cation size but (ii) the high M^{2+} concentration would indicate D increases with increasing cation size. More work is needed to clarify this point.

5.4 Thermal Conductivity (K)

Many silicates are considered to be *semitransparent* media through which heat is transferred by several mechanisms (Chapter 4.5), namely, (i) *phonon* or *lattice conduction*, (ii) *convection*, and (iii) *radiation conduction* (k_R , a mechanism that involves absorption of IR radiation and reemission). This complex situation poses severe measurement problems. One can minimize convection by using transient techniques such as the laser pulse (LP) and transient hot wire (THW) methods. However, the measured thermal conductivity (k_{eff}) for silicates may contain a k_R contribution of unknown magnitude. For an *optically thick sample* (defined as $\alpha*d > 3$ where $\alpha*$ = absorption coefficient and d = thickness of sample), k_R can be calculated ($k_R = 16\sigma n^2 T^3 / 3\alpha*$ where n is the

refractive index and σ the Stefan–Boltzmann constant); contributions from k_R rise sharply with increasing temperature owing to the T^3 dependence.

There is some uncertainty in measured thermal conductivity values [12] since:

- i) At the present time, there are large differences between the values obtained with the laser pulse (k_{LP}) and transient hot wire (k_{THW}) methods for temperatures higher than 1000 K (Figure 8); reported values for liquid slags of similar composition indicate $k_{LP} \approx 5 k_{THW}$. At this time no values of k can be recommended for slags above 1000 K.
- ii) One reduces contributions to radiation conduction (k_R) by (i) adding transition metal oxides (e.g. FeO, NiO), which increase the absorption coefficient of solid and liquid slags, and (ii) by promoting crystallization in solid slags since crystals, grain boundaries, and pores scatter IR radiation.

The temperature dependences of the thermal conductivities obtained with the LP and THW methods are similar below 1000 K but diverge markedly at higher temperatures (Figure 8a). At a certain point (denoted the critical temperature, $T_{crit} \approx 1000$ K), k_{THW} values drop sharply with increasing temperature, whereas k_{LP} values exhibit a gentle rise with increasing temperature up to T_{liq} , before showing a small decrease for the liquid.

This critical temperature occurs for k_{THW} values at the temperature where the viscosity attains a value of 10^6 dPa s, i.e. midway between the *softening temperature* (where the sample can no longer support its own weight) and the *flow point* (Chapter 1.1, [12, 16]). Furthermore, measurements of k_{THW} indicate that values of k_{298} increase with both increasing polymerization (Q) and increasing cation field strength (z/r^2). These findings are consistent with the view that the magnitude of the thermal conductivity (k_{THW}) of the solid is associated with the *rigidity* of the silicate network.

Figure 8 Thermal conductivity of $Na_2O-CaO-SiO_2$ slags of similar composition. (a) As a function of temperature; curve = k_{THW} ; o = k_{LP} . (b) As a function of $\log_{10}$ viscosity for four different slags; dotted lines (from left) T_{flow} ; T_{soft} ; T_{liq} .

6 Thermodynamic Properties

6.1 Thermal Expansion Coefficient

Referring to Chapter 3.5 for details, we just remind the reader that the coefficient of volume thermal expansion is given by $\alpha_V = (V_T - V_{298})/[V_{298} (T - 298)]$ where V is the molar volume.

The values of α_V for liquid silicates [9] decrease with:

- i) Increasing polymerization (i.e. Q).
- ii) Increasing field strength (z/r^2) of the cation.

The above factors also affect the thermal expansion of the solid. Values of α_l and α_V for both glassy and crystalline phases are similar from 298 K to T_g , but the transition from glass to supercooled liquid is accompanied by a large increase in α ($\alpha > T_g \approx 3 \alpha < T_g$). In contrast, α values for the crystalline phase maintain a smooth relation with increasing temperature.

6.2 Density (ρ) and Molar Volume (V)

The density (ρ) and molar volume (V) are linked via

$$\rho = \frac{M}{V}, \quad (14)$$

where M is the molecular weight of the slag and the effect of temperature on V is given by

$$V_T = V_{298} [(1 + \alpha (T - 298))]^3. \quad (15)$$

The molar volume of a slag is slightly affected by the degree of polymerization. Reasonable estimates of the molar volumes of liquid slags can be calculated from partial molar volumes (Eq. 16) for the various slag constituents, denoted 1, 2, and 3, but a plot of $(XV)_{\text{SiO}_2} - X_{\text{SiO}_2}$ exhibits a negative departure from linearity implying compaction in the structure. Thus polymerization results in reduction of the molar volume (or increase in density). The effect of Al_2O_3 on the molar volume is the reverse of that for SiO_2 :

$$V = \sum (XV)_1 + (XV)_2 + (XV)_3 + \dots \quad (16)$$

Crystalline phases have higher densities than glassy slags. Crystallization of a glassy slag results in some shrinkages causing porosity in the slag. There is an increase in molar volume (ΔV^{fus}) when crystalline slags melt, but values of ΔV^{fus} for the supercooled liquid are much lower because of the expansion associated with the enhanced α values above the glass transition.

6.3 Thermodynamics and Liquidus Temperature

Thermodynamic properties are affected by the field strength (z/r^2) of the cations present:

- i) *Phase diagrams* for MO-SiO_2 systems exhibit miscibility gaps at high SiO_2 contents, the width of the gap increasing with increasing field strength of the cation (z/r^2), i.e. $\text{Mg} > \text{Ca} > \text{Sr}$ (Chapter 5.2).
- ii) The *liquidus temperatures* (T_{liq}) of $\text{M}_2\text{O-SiO}_2$ and MO-SiO_2 systems tend to decrease with decreasing field strength of the cation.
- iii) The *activity coefficients* of SiO_2 ($f_{\text{SiO}_2}^*$) in $\text{M}_2\text{O-SiO}_2$ and MO-SiO_2 systems increase as the field strength of the cation decreases (i.e. in the hierarchy of f^* , $\text{K}_2\text{O} > \text{Na}_2\text{O} > \text{Li}_2\text{O} > \text{BaO} > \text{SrO} > \text{CaO} > \text{MgO}$). In meta-aluminous aluminosilicates (i.e. $X_{\text{Al}_2\text{O}_3} = X_{\Sigma\text{M}_x\text{O}}$), the order changes since $f_{\text{SiO}_2}^*$ then increases as the field strength of the charge-compensating cations (i.e. in the order $(\text{Ca} > \text{Na} > \text{K})$ and with decreasing $2\text{Al}/(2\text{Al} + \text{Si})$ ratios [8, 9].
- iv) Values of the *enthalpy of solution* of meta-aluminous aluminosilicates in lead borate become more negative (i.e. more thermodynamically stable) as (z/r^2) for the cations (doing the charge balancing) decreases (i.e. in the hierarchy $\text{K} > \text{Na} > \text{Li} \approx \text{Ba} > \text{Sr} > \text{Ca} > \text{Mg}$) [17].
- v) The *entropy of fusion* (ΔS^{fus}) for crystalline phases increases with (i) decreasing SiO_2 content and (ii) increasing field strength (z/r^2) of the cation [8, 9].
- vi) The *heat capacity* (C_p) and *enthalpy* ($H_T - H_{298}$) for crystals can be estimated in most cases to $\pm 2\%$ from composition-independent partial molar quantities; routines are available to estimate C_p and ($H_T - H_{298}$) for the supercooled liquids [9].

6.4 Sulfur and Phosphorus Capacities

Industrially, considerable effort is devoted to minimizing sulfur and phosphorus levels in molten metals because of the aforementioned deleterious effects of these elements. The concepts of S and P capacities (denoted C_S and C_P) have been defined to characterize the ability of a specific slag to withdraw these elements from the molten metal. These capacities are thus directly related to the partition coefficients, which for sulfur is, for instance, $L_S = [(\% \text{S})_{\text{sl}} / (\% \text{S})_{\text{m}}]$. The complication here is that the speciation of S and P must be taken into account when reactions between the molten metal and slag are considered and their equilibrium constants evaluated.

In the slag, sulfur coexists as sulfide and sulfates so that one has [18, 19]

$$K_1 = \left(\frac{a_{\text{S}}^{2-}}{a_{\text{O}}^{2-}} \right) \left(\frac{p_{\text{O}_2}}{p_{\text{S}_2}} \right)^{0.5}, \quad (17b)$$

$$K_2 = \left(\frac{a_{\text{SO}_4}^{2-}}{a_{\text{O}}^{2-}} \right) \left(\frac{p_{\text{O}_2}}{p_{\text{S}_2}} \right)^{0.5} \quad (18b)$$

Because the oxygen activity a_{O}^{2-} is high, however, in a first approximation, the low sulfur activity can be assumed to be constant, $a_{\text{O}}^{2-} = \gamma_{\text{S}}$, so the sulfur and sulfide capacities (C_{S}) simplify to [18]

$$C_{\text{S}} = \text{wt } \% \text{S} \left(\frac{p_{\text{O}_2}}{p_{\text{S}_2}} \right)^{0.5}, \quad (19)$$

$$C_{\text{SO}_4}^{2-} = \frac{\text{wt } \% \text{SO}_4^{3-}}{\left\{ (p_{\text{O}_2})^{1.5} (p_{\text{S}_2}) \right\}^{0.5}}. \quad (20)$$

Likewise [20], the analogous reactions and capacities for phosphide and phosphate capacities (C_{P}^{3-} and $C_{\text{PO}_4}^{3-}$) are given by

$$0.5\text{P}_2 + 1.5\text{O}_{\text{sl}}^{2-} = 0.75\text{O}_2 + \text{P}_{\text{sl}}^{3-}, \quad (21a)$$

$$C_{\text{P}}^{3-} = \frac{\text{wt } \% \text{P}^{3-} p_{\text{O}_2}^{0.75}}{p_{\text{P}_2}^{0.5}}, \quad (21b)$$

$$0.5\text{P}_2 + 1.5\text{O}_{\text{sl}}^{2-} + 1.25\text{O}_2 = \text{PO}_4^{3-}{}_{\text{sl}}, \quad (22a)$$

$$C_{\text{PO}_4}^{3-} = \frac{\text{wt } \% \text{PO}_4^{3-}}{(p_{\text{O}_2}^{1.25} p_{\text{P}_2}^{0.5})}. \quad (22b)$$

In practice, high S and P capacities thus are achieved with high-basicity slags.

6.5 Surface Tension (γ) and Interfacial Tension (γ_{msl})

Surface and interfacial tensions are not *bulk* properties because they are affected by *surfactants*, which tend to occupy preferentially the surface layers of the sample; typical ones are *soluble* S and O in the metal phase and B_2O_3 , K_2O , CaF_2 in silicates. The temperature derivative $d\gamma/dT$ tends to switch gradually from a negative to a positive value with increasing SiO_2 content; the crossover point is near $X_{\text{SiO}_2} > 0.5$. In metal processing, the interfacial tension (γ_{msl}) owes its great importance to the fact that it is a major factor in slag/metal kinetics and in slag entrapment. It can be calculated from

$$(\gamma_{\text{msl}}) = (\gamma_{\text{m}}) + (\gamma_{\text{sl}}) - 2\phi(\gamma_{\text{m}} \gamma_{\text{sl}})^{0.5}, \quad (23)$$

where the interaction coefficient (ϕ) increases with increasing Gibbs energy of formation per mole O for the oxides present. Because surface tension tends to be three or four times higher for the metal phase than for silicate melts, it is largely controlled by the former phase and hence is sensitive to the *soluble* O and S contents in the metal.

6.6 Comparison of Property Values for Metallurgical and Coal Slags and Molten Minerals

Property values for various slags are compared with those for minerals in Table 2. It can be seen that the viscosity increases with increasing degree of polymerization (Q). A similar comparison of the activation energy terms (B_{A}) would show an identical trend. The principal differences between the property values of glasses and minerals and those of metallurgical slags are due to the fact that the latter have a loose structure compared with the 3-D framework of minerals.

7 Perspectives

In the past, measurements of physical properties for slags have proved useful in understanding the mechanisms causing problems in process control and product quality. That remains the case, but a new demand for slag property data is likely to emerge in the future. Over the last 30 years, mathematical modeling of processes has improved to the point that they can now give insight into the mechanisms responsible for process problems. A good example is the model of the continuous casting of steel (Figure 3), which couples fluid flow, heat transfer, and the solidification of the steel shell [19, 20]. This model has not only correctly predicted heat fluxes and the consumption of slag but also revealed the mechanisms underlying defect formation (e.g. slag entrapment) (Figure 2) and the formation of oscillation marks [20]. The model actually allows one to *see into the mold* even at a very high temperature of 1900 K.

Mathematical modeling of processes will prove an ever-more important tool in improving process control and product quality in the future. However, these models need good, reliable property values for both slag and metal phases as input data (cf. Chapter 1.7 for analogous models in glassmaking). Physical property measurements are both time consuming and costly. There is a vast range of slag compositions used in metallurgical processing, and compositions tend to vary on a daily basis. Consequently, it is unrealistic to carry out property measurements on all slags. Thus, it is necessary to develop mathematical models to calculate reliable property values from slag chemical composition data (which is available on a routine basis). This will be a major challenge for the future and will require the model to describe not only the effect of polymerization but also the various cation effects, and this, in turn, will require a reliable description of the slag structure.

A final point should be noted. The continuous drive for improved process efficiency has caused the recycling of slag wastes (e.g. in cements; cf. Chapter 9.9) and energy capture from slags to become very active areas of research in recent years.

Water Glass

Hans Roggendorf

Martin-Luther-Universität Halle-Wittenberg, Institute of Physics, Halle (Saale), Germany

1 Introduction

By water glass one designates not only alkali-rich silicate glasses but also the liquid phases obtained either when these glasses are dissolved into water or when a silica phase is dissolved in alkaline lyes. They are also called “soluble silicates.” Water glass has in fact a long history as it was first mentioned by the Flemish chemist and physician Joan Baptista van Helmont who reported in 1648 in his *Ortus medicinae* [1] that “if one melts a fine powder of glass with a large amount of alkali and exposes it in a humid place, one will presently find that all the glass dissolves into a water” (see Chapter 10.11). But a long-standing practical interest in this material was raised much later in the 1820s when the Bavarian chemist and mineralogist Johann Nepomuk Fuchs (1774–1856) described applications of materials he termed himself *water glasses* such as “protectant against the rapid propagation of fire in theaters, as binder and paint films” [2]. His potassium silicate glasses contained more silica than van Helmont’s and thus had the interest of being stable against moist atmospheres but still soluble in water.

To optimize many more practical applications, the chemical composition of water glass has since then been varied not only through changes in the nature and concentration of the alkali cation but also through the incorporation of ammonium ions. As a result, this silicate family has become one of the most important inorganic chemicals, being added to detergents, cements, paints, adhesives, and binders, serving in water treatment and mineral ore flotation, or used as a starting product in the fabrication of ceramics or of specialty minerals such

as zeolites. Water glass provides concentrated, reactive silica in a liquid phase with a buffered alkalinity ensured by the weakly bonded alkalis. Hence, it has the great advantage of offering the versatility of silicate materials in the context of aqueous chemistry.

The composition of water glass is most simply characterized by the $\text{SiO}_2/\text{M}_2\text{O}$ ratio ($\text{M} = \text{Li}, \text{Na}, \text{K}$) on either a mol (R_m) or a weight (R_w) basis. (Note that $R_m = R_w \cdot F_M$, where the F factors are the ratios of the molar masses of the relevant alkali oxide and silica, namely, $F_{\text{Na}} = 1.032$, $F_{\text{K}} = 1.566$, and $F_{\text{Li}} = 0.497$). In 1998 the world production was estimated to lie between 3×10^6 and 4×10^6 tons, the majority in the form of sodium water glass. More recent data for 2010 claim the production of soluble silicates with a content of 740 000 tons of SiO_2 in Western Europe alone.

In this chapter we will thus review the production, structure, basic physical and chemical properties, and uses of these basic materials.

As a complement, we refer the reader to a review on older literature by Vail [3] and to more recent papers by Iler [4] and Falcone [5]. Vail covered the whole range from science via technology to application available at his time, Iler treated soluble silicates in his outstanding book on silica chemistry from a more fundamental side, and Falcone took up new developments with a focus on structure. As for production processes, additional basic information can be found in handbooks on technical chemistry (e.g. [5]).

2 Fabrication of Water Glass

2.1 Process I: Glass Synthesis with Subsequent Dissolution in Water

The most important fabrication process of liquid water glasses is melting of raw materials to produce alkali silicate glasses, which are subsequently dissolved in water.

Figure 1 Process scheme for the productions of water glass and related materials.

The majority of the sodium water glasses and nearly all potassium water glasses are made by this process. As a matter of fact, the chemical durability of alkali silicate glasses with the same stoichiometry increases so much in the order $K \ll Na \ll Li$ [6] that lithium water glasses cannot be prepared by this process. In addition, Li-rich silicates such as lithium metasilicate (Li_2SiO_3) are poor glass formers, which also hampers dissolution because, for a given composition, the solubility in water is higher for the glass phase than for its crystalline counterparts.

The main steps of the process are sketched in Figure 1. Silica, alkali carbonates (e.g. Na_2CO_3 and K_2CO_3), alkaline brines ($LiOH$, $NaOH$, KOH), and water are used as raw materials. With silica having several polymorphs of economic interest, the very common α -quartz form (also known as low quartz) is the usual source for both the melting process and hydrothermal dissolution in alkaline lyes. Synthesis of sodium or potassium silicate glasses requires fast and total dissolution of quartz, which is achieved with melting temperatures between 1100 and 1400 °C [7]. The alkali oxides act as flux for silica. In most cases continuously operating melting tanks with regenerative heat recovery systems are used, but their lifetime is limited because high-alkali melts, the alkaline gas components evaporating from the melt into waste gases, and fine dusts are all strongly corrosive. When melting is completed, the fluid melt is often poured on metallic chain belts with molds and cooled rapidly to glass cullets or lumps. Typical lumps have a cross section of about $8 \times 8 \text{ cm}^2$ and a thickness of 3 cm. For some applications the glass lumps are ground, sieved, and screened in a dry atmosphere to yield anhydrous glass powders.

Thanks to their low chemical durability, alkali silicate glasses in the form of lumps or cullet rapidly dissolve in water to yield highly concentrated liquid water glasses.

In 2000 about 70% of liquid water glasses in Western Europe were produced with this process. Dissolution is performed as a batch process at temperatures up to 170 °C [7]. Rotating autoclaves or standing digesters with stirring or circulating liquid phase suitable for high pressures are applied. Above 100 °C the dissolving units have to oppose high water vapor pressure and are often heated with steam [7].

Because the melting tanks and dissolver units are inevitably corroded by the glass, they contaminate it with impurities that add up to those present in the raw materials or come from the fossil fuels burned in the process. These impurities influence the properties and applicability of the liquid water glasses. Highly charged cations are problematic because they can trigger the precipitation of silicate crystals. A filtering step with a cutoff in the high nm range (e.g. 450 nm) thus usually increases purity. For commercial liquid water glasses, typical impurities are CaO (not detected up to 150 ppm), MgO (n.d. to 40 ppm), Al_2O_3 (80–1700 ppm), Fe_2O_3 (20–120 ppm), and TiO_2 (60–200 ppm). As described by the patent literature, higher purities, e.g. for applications in electronics, can be achieved by filtration in the lower nanometer range, ion exchange, and electrochemical methods.

One can then adjust the composition of the water glass by dilution with or evaporation of water, by ion exchange to remove alkalis, or by mixing liquid water glass with alkaline lyes. If needed, one can also increase the R_m ratio of the product by dispersing silica materials with high specific surface area in liquid water glass or by combining colloidal silica with glass lumps upon dissolution.

The dissolution process itself depends on glass composition, temperature, pH, and concentration of the liquid water glass. It begins with an exchange of alkalis for protons, which causes the pH to increase to values higher

than 9. Under these pH conditions, a steady state is established for network dissolution and ion exchange. At higher temperatures the silicate network disintegrates directly into colloidal silica [8].

2.2 Process II: Dissolution of Silica Phases in Alkaline Lyes

The second process used to fabricate water glass bypasses glass fabrication to rely instead on dissolution of silica phases in alkaline lyes. A variety of silica phases such as quartz, cristobalite, tridymite, calcined rice husk, and vitreous or pyrogenic silica can dissolve to a certain degree. Temperatures between 160 and 250 °C in pressure-tight dissolution units or autoclaves are applied. By dissolving quartz sand in NaOH lyes one can reach R_m values up to 2.7 [7]. Cryptocrystalline and vitreous or colloidal silica, which have a lower chemical durability than α -quartz, can be used to enhance the rate of the dissolution process and to increase the R_m value of the products.

In the case of potassium water glass, the R_m ratios attainable by hydrothermal dissolution are too low for technical applications. One reason is the crystallization of KHSi_2O_5 under hydrothermal conditions as reported already by Morey and Fenner [9].

Lithium water glasses are prepared by dissolution of silica phases with a high specific surface area in LiOH lyes [7]. To prepare ammonium water glasses [10], aqueous ammonium hydroxide solutions are first mixed with dilute sodium water glass, and then sodium is extracted by ion exchange. If ammonia is replaced in that process by amines like monoethanolamine, one obtains quaternary ammonium silicates. Quaternary ammonium is an organic cation with a +1 charge consisting of nitrogen bonded covalently to four alkyl or aryl groups.

2.3 Production of Crystalline Sodium Silicates

Anhydrous sodium metasilicate (Na_2SiO_3) can be produced as a crystalline material through reaction of silica with sodium carbonate from 850 °C, the melting point of soda, to temperatures slightly below its own melting point at 1018 °C or through crystallization of a quite corrosive glassmelt. Alternatively, the anhydrous sodium metasilicate can be prepared through drying of sodium water glass. Sodium silicate hydrates are obtained by direct hydration of the anhydrous metasilicate or by drying sodium water glass at lower temperatures. Layered sodium silicates are produced by spray drying or by crystallization from seeded (with the desired crystalline product) concentrated liquid water glasses at temperatures above 70 °C. In many cases a heat treatment at temperatures of up to 800 °C is necessary to obtain the desired

modifications. The reaction products are ground, sieved, and screened after drying [11].

3 Materials and Chemical Stability and Structure

3.1 Alkali Silicate Glasses

Alkali silicate glasses contain one network former and one network modifier (see Chapter 2.4). Each sodium atom introduced into the structure creates one nonbridging oxygen, which decreases the polymerization degree of the structure:

Important consequences of this network depolymerization are lower liquidus and melting temperatures and lower chemical durability of the glasses.

The structure of alkali silicate glasses has been investigated with various methods like NMR spectroscopy, molecular dynamics simulations, or scattering (Section II). Some investigations indicate the formation of nanoscopic clusters, e.g. sodium-rich channels and silica-rich islands (see Chapter 2.5). Such a microstructure provides paths for the intrusion of molecular water or protons and explains the direct disintegration of the glass into colloids described in [8].

At high silica content this nanoscopic segregation gives way to metastable phase separation with a miscibility gap that increases in the order $\text{K} < \text{Na} < \text{Li}$ (Chapter 5.2). For sodium silicates, the sodium-rich branch of the solvus is found at 20 mol % Na_2O , which thus represents the lowest Na_2O content possible for sodium silicate glasses applicable for the production of liquid water glass.

3.2 $\text{Na}_2\text{O}-\text{SiO}_2-\text{H}_2\text{O}$

Liquid sodium water glasses are the most common types. Standard products have R_m values of 2 ("alkaline" water glass") and 3.3 ("neutral water glass"), but the whole ranges are $R_m = 2-2.2$, 3.3-3.5, and 3.9-4.1, with SiO_2 content going up to 35 wt %. The compositions of some important materials are shown in Figure 2, whereas a few basic properties [12] are listed in Table 1 for compositions of practical interest. Phase equilibria have been investigated in the ternary system $\text{Na}_2\text{O}-\text{SiO}_2-\text{H}_2\text{O}$ (e.g. [13]). At 200 °C a liquid water glass with 27.5 wt % SiO_2 and $R_m = 2.83$ is, for instance, in equilibrium with α -quartz, in agreement with the findings that liquid sodium water glasses with $R_m < 2.7$ can be produced by hydrothermal dissolution of low quartz. At higher temperatures, the solubility of silica decreases.

Crystalline sodium metasilicate hydrates of formula $\text{Na}_2\text{O} \cdot \text{SiO}_2 \cdot n\text{H}_2\text{O}$ with $n = 0, 5, 8$, and 9 are common [5].

Other crystalline materials are the so-called layered sodium silicates whose structure consists of layers of SiO_4 tetrahedra interconnected via sodium ions. One type of these layered sodium silicates comprises several modifications of the disilicate ($\text{Na}_2\text{O} \cdot 2 \text{SiO}_2$). Especially the $\delta\text{-Na}_2\text{O} \cdot 2 \text{SiO}_2$ modification is used for ion exchange of alkalis against water hardeners like Mg^{2+} or Ca^{2+} . Other types of layered sodium silicates have higher R_m ratios. Some of them occur in natural salt lakes, e.g. magadiite ($\text{Na}_2\text{Si}_{14}\text{O}_{29} \cdot 11 \text{H}_2\text{O}$) or kenyaite ($\text{Na}_2\text{Si}_{22}\text{O}_{45} \cdot 10 \text{H}_2\text{O}$). Synthetic variants with comparable compositions are described in the patent literature for applications based on their intercalation abilities for surfactants in detergents.

3.3 $\text{K}_2\text{O}\text{--SiO}_2\text{--H}_2\text{O}$

The R_m ratio of commercial liquid potassium water glasses varies between 3.3 and 3.5 and 4.0–4.3, with SiO_2 contents reaching 25 wt %. The system $\text{K}_2\text{O}\text{--SiO}_2\text{--H}_2\text{O}$ was investigated by Morey and Fenner above 200°C [see ref. 9]. At

Figure 2 Ternary diagram $\text{Na}_2\text{O}\text{--SiO}_2\text{--H}_2\text{O}$; crystalline $\text{Na}_2\text{O} \cdot \text{SiO}_2 \cdot n\text{H}_2\text{O}$ with different values of n at the center; M, magadiite; K, kenyaite.

200°C , up to 24 wt % potassium silicate with $R_m = 2.0$ is dissolved in a liquid that is in equilibrium with potassium disilicate monohydrate ($\text{K}_2\text{Si}_2\text{O}_5 \cdot \text{H}_2\text{O}$) and potassium tetrasilicate monohydrate ($\text{K}_2\text{O} \cdot 4 \text{SiO}_2 \cdot \text{H}_2\text{O}$ or KHSi_2O_5).

3.4 Other Types of Water Glass

Lithium-containing water glasses with R_m ratios between 3 and 9 and SiO_2 contents up to 20 wt % are produced by dissolution of ion-exchanged silica gels or colloidal silica in LiOH lyes [7]. Lithium cations probably stabilize larger amounts of silica colloids, thus allowing products to be made with higher R_m ratios combined with appreciably low viscosity.

Besides, ammonium-bearing water glasses have been introduced by Weldes [10]. Here defined as the molar $\text{SiO}_2/(\text{NH}_4)_2\text{O}$ ratios, R_m values of these materials range from 2 to 6 and SiO_2 contents from 6 to 12 wt %. Organic ammonium silicates or quaternary ammonium water glasses ($\text{A}_4\text{N} \cdot x\text{SiO}_2$, A: butyl, ethyl, etc.) have also been synthesized. Mixed alkali water glasses that contain more than one type of alkali are described in the literature, mainly for binder applications that require the higher chemical durability provided by adding lithium water glass.

3.5 Solubility of Silica at High pH

Sometimes molecular and colloidal solubilities are distinguished. Colloids are solid particles dispersed in a continuous medium with sizes comprised between 1 and 100 nm. Silicate molecules with more than 10 SiO_2 units have already diameters in the colloidal size range. Therefore, a distinction between large molecules (or macromolecules) and colloids is probably not significant. Nevertheless, molecules or colloids are treated separately here because they require different characterization techniques.

The older literature on the solubility of silica modifications was evaluated by Iler [4]. The solubility of silica depends on coexisting equilibrium phase, temperature, pressure, pH, and size of solid particles. Iler reported that the solubility of quartz is about 10 ppm under neutral conditions at room temperature. Other silica

Table 1 Composition and properties of liquid alkaline silicate water glasses [12].

R_m	SiO_2	Na_2O	K_2O	density ρ	Dynamic viscosity η	pH
	in wt %			in g/cm^3	in mPa s	
2.0	24.7	12.3		1.437	44.7	13.0
3.3	25.2	8.0		1.327	21.2	12.1
3.3	24.4		12.4	1.358	24.3	12.5
4.0	19.9		8.3	1.239	8.7	12.1

modifications may have higher solubilities. Their solubilities increase with temperature and pH. That of Si(OH)_4 reaches about 1000 ppm under hydrothermal conditions at 300 °C. The solubility of amorphous silica is higher than that of α -quartz. Si(OH)_4 is a weak acid which dissociates especially at basic pH:

thereby deprotonating silanol groups and creating a negative charge. Iler [4] calculated thermodynamic equilibria between Si(OH)_4 , SiO(OH)_3^- , and $\text{SiO}_2(\text{OH})_2^{2-}$ at 25 °C. Above pH 9 the solubility of silica increases because of the pH-dependent formation of the silicic anions mentioned above. Iler restricted his calculations to pH values below 10.5. An extrapolation of his data to the higher pH range of liquid water glasses yields solubilities that are probably too large (Figure 3). More detailed information can be derived on solubility fields from the data of Falcone et al. [14] and Stumm and Morgan [15]: in domain A - (Figure 3, inset), alkali silicate solutions are unstable; in domain B, liquid water glasses containing "multimeric" silica are in contrast stable; and in domain C, alkali silicate solutions containing only monomeric silica species are found. Whereas multimeric silica comprises large molecules and colloidal silica, the thermodynamic calculations made by Iler considered only monomeric species. Because the line representing the total silica content of monomeric species in Figure 3 lies within domain B, it appears that the extrapolation toward higher pH values does not agree totally with experimental data.

3.6 Structure of Liquid Water Glass at a Molecular Scale

Liquid water glasses contain silicic acid molecules Si(OH)_4 and anionic silicic species. Investigations by Raman and infrared (IR) spectroscopy [14] confirm Iler's thermodynamic calculations and indicate that SiO(OH)_3^-

and $\text{SiO}_2(\text{OH})_2^{2-}$ are the main anions at basic pH values, whereas Si(OH)_4 prevails in the acidic region [4]. These anions and molecules reflect the tetrahedral structure typical of silicates and can be regarded as monomers building up larger units by condensation reactions of the following type:

Theoretically, there is no limit to condensation, and also large molecules or colloids are formed by these reactions. The molecules can ionize in aqueous solutions. Charge compensation is then provided by cations such as H^+ or M^+ ($\text{M} = \text{Li}, \text{Na}, \text{K}, \text{etc.}$).

One of the first methods to study the structure of oligomeric silicate anions was trimethylsilylation. Upon addition of trimethylsilane to the solution, the protons of OH groups are replaced by SiMe_3 ($\text{Me} : \text{CH}_3$), which inhibits further reactions of silanol groups and allows silicate anions to be separated by chromatography. Andersson et al. [16] identified in this way anions with up to eight silicon atoms. These investigations have been supplemented with ^{29}Si NMR spectroscopy. Different silicate anions with up to 12 silicon atoms have been detected in dilute water glasses enriched in ^{29}Si . Investigations on liquid water glasses with technical compositions allowed the Q^n speciation to be determined, where Q^n denotes silicon atoms connected via bridging oxygens to n other silicon atoms (Chapter 2.4). Bahlmann et al. [17] made quantitative ^{29}Si NMR measurements and showed that a sodium water glass with 30 wt % SiO_2 and $R_m = 3.4$ contains 0.6 % Q^0 , 4.7 % Q^1 , 29.8 % Q^2 , 50.3 % Q^3 , and 14.6 % Q^4 units, all Q^4 and part of Q^3 units building up colloidal silica at the surface of which the latter are present.

Additional information can be obtained by Raman and IR spectroscopy. Especially the spectral range from 800 to 1200 cm^{-1} can be investigated to identify and quantify silicate species in liquid water glasses. Falcone et al. [14]

Figure 3 Concentrations of silicate species in equilibrium with colloidal silica as a function of pH according to Iler [4]. Inset: stability fields of monomeric (C), oligomeric (B), and polymeric (A) liquid water glasses according to Falcone et al. [14] and Stumm and Morgan [15].

applied this means and showed that the concentration of monomeric silica stays constant during further polymerization that they induced by replacing sodium with tetramethylammonium.

3.7 Structure of Liquid Water Glass at a Colloidal Scale

Colloids in liquid water glasses are supposed to consist mainly of silica. Iler [18] argued that alkalis are necessary to stabilize the colloidal surface. The colloid stability depends on an electric double layer formed of negatively charged deprotonated silanol groups and positive sodium ions that are partially hydrated. He concluded that alkali concentration limits the surface area of colloids, which act like micelles in tenside solutions by “hiding” the silica that cannot be stabilized by charge-compensating alkali ions. One consequence is that liquid water glasses with higher R_m values but identical SiO_2 content have fewer and smaller colloids because of their higher alkaline content. Iler applied static light scattering and detected 10% monomers, 75% colloids with a diameter of about 1.8–1.9 nm, and 15% oligomers in concentrated liquid sodium water glass ($R_m = 3.2$). Newer investigations by dynamic light scattering [19] have shown the existence of particles exhibiting several maxima in their size distribution between 1 and 100 nm even in strongly dilute sodium water glasses. This is demonstrated in Figure 4 for a sodium water glass with $R_m = 2.2$, a composition supposed to be less liable to colloid formation than those with smaller sodium concentrations. The larger colloids probably formed by aggregation of smaller ones and are deformable since they can pass filters with pore sizes smaller than their particle size [12]. This study also showed that the applied synthesis routes – dissolution of glass with $R_m = 2.0$, dissolution of quartz ($R_m = 2.0$), and dissolution of a glass with $R_m = 3.3$ and subsequent mixing with NaOH lyes – yield concentrated liquid water

glasses that have almost the same structure at a molecular scale but present some differences in the particle size distribution of colloids.

Tognonvi et al. [20] combined ^{29}Si NMR spectroscopy and small-angle X-ray scattering to describe solvated silicate ions to conclude that the primary building unit in concentrated liquid water glasses with $R_m = 3.4$ is a neutral $\text{Si}_7\text{O}_{18}\text{H}_4\text{Na}_4$ complex with a size of 0.6–0.8 nm. This complex dissociates into silicate and sodium ions when water glass is diluted. The silicate ions then condensate to larger units containing two to eight of these complexes, a finding that is in agreement with colloid sizes between 0.8 and 2 nm, which have been found by light scattering.

The aforementioned surface stabilization depends on pH and alkali concentration. Changing these parameters may destabilize the colloids and lead to flocculation.

According to phase diagrams, most of liquid alkaline water glasses are not in thermodynamic equilibrium. On the other hand, as shown above, different synthesis routes yield nearly identical structural results on a molecular scale [12]. Hence, liquid water glasses should be in metastable equilibrium at the temperatures that are typical of dissolution processes. This equilibrium is characterized by ongoing hydrolysis and condensation reactions. To obtain a stable thermodynamic equilibrium, the precipitation of the crystalline equilibrium phase would be required. At ambient temperature, however, the kinetics of structural rearrangements by hydrolysis and condensation becomes too slow probably because the concentration of monomeric units decreases with temperature. Additionally steric barrier effects and stabilization of colloidal dispersions by an electrostatic double layer at their surface are more effective at lower temperatures because the kinetic energy of the colloids then is lower.

In summary, the structure of concentrated liquid water glasses can be described as complex colloidal suspensions

Figure 4 Mass content of colloidal size classes measured by dynamic light scattering [19] as a function of sodium oxide content for liquid sodium water glass with $R_m = 2.2$; water glass diluted by mixing with deionized water, measured within two hours after mixing; radius of colloids included in the figure.

in aqueous alkali silicate solutions. Since sols are colloidal suspensions, liquid water glasses can be also addressed as alkali silicate sols.

4 Properties of Water Glass

4.1 Refractive Index, pH, Density, and Viscosity

The refractive index, pH, density, and viscosity are basic properties that can be used for quick quality control [3, 12] (see Table 1 for standard materials). The refractive index and density are in a first approximation additive functions of composition in terms of the three main components M_2O , H_2O , and SiO_2 [3], but they vary slightly with impurity concentration and thermal history of the liquid water glasses from synthesis onward.

When measured against the sodium content of the solutions, the near constancy of the pH between 10 and 13 at high alkali concentration indicates that liquid water glasses act as a pH buffer (Figure 5), a property useful in many applications where liquid water glass provides an alkali reservoir under intermediate basic conditions. A look at the pH of concentrated solutions (Table 1) shows that the OH^- concentration and the overall Na content of the liquid water glass are not equal. A sodium water glass with $R_m = 3.3$ has a Na concentration of 1.9 mol/l. If all Na were acting as counterions for OH^- groups, a pH of 14.3 would result whereas the measured pH is 12.1. The majority of Na thus is adsorbed on negatively charged surface sites to stabilize colloidal silica.

Viscosity measurements of dilution series of liquid water glasses show a dependence typical for spherical particles [21]. Although dilute liquid sodium water glasses have a Newtonian viscosity, shear thickening has been observed at higher concentrations.

Figure 5 Effect of dilution with deionized water on the pH of sodium water glass; data from [19].

4.2 Chemical Reactivity

The chemical reactivity of water glasses depends on their composition and on thermal history, which influences the particle size distribution of the colloids. In reactions where they provide silicate ions or alkalinity, the depolymerization reactions of oligomeric and colloidal silica are of importance. The chemical reactivity can be characterized by the reaction of $Si(OH)_4$ with molybdic acid to the yellow silicomolybdate complex, where the optical absorption is a measure of the concentration of the silicomolybdate complex. Polymeric silica has to depolymerize first before it can react with the molybdic acid. Therefore, the kinetics of the silicomolybdate formation can be used to characterize the depolymerization kinetics. The literature on that topic was reviewed by Iler [4]. The polymerization takes place at room temperature within 10–30 minutes and is usually fast enough. The adsorption of multivalent metal ions on polymeric silica has been discussed by Falcone [5], who states that the absorption efficiency increases with polymerization degree.

5 Applications of Water Glass

An overview on uses of soluble silicates is given by Falcone [5]. Soluble silicates are “commodity chemicals” produced mainly as intermediate products. Half of them are applied for the synthesis of silicate materials; 40% are used as detergents, in the paper industry, and for soil stabilization; and 10% are used as additives to other products or as binders.

5.1 Liquid Water Glass and Amorphous Materials: Gels, Silica Sols, Precipitated Silica, and Dried Water Glasses

Liquid water glass is used as alkaline buffer, e.g. in the paper bleaching process with H_2O_2 as bleaching agent, as accelerator in concrete where it hardens the cement within 15 minutes, and as binder. Another application is the conservation of building stones, especially with potassium or lithium water glasses. When added to particle suspensions (ore, ceramic particles), liquid water glasses can interact with the surface of the particles and influences pH. These changes can be applied to foster filtration or flotation processes and to stabilize and liquefy ceramic suspensions.

Sodium water glasses are the common precursors for the preparation of silica materials. When neutralizing liquid water glasses with acids, the silicates polymerize [4, 5] to a sol of colloidal silica (basic pH 7–10, no salts present) or to more linear structures (pH < 7 or at slightly basic conditions with salt being present) forming a gel. Wet

gels can be used as templates for reactions or for crystallization processes. Dried gels are called xerogels and are powders with high specific surface areas and nanosized pores, which make them efficient desiccants or adsorbents. To produce aerogels, the wet gels have to be gently dried to avoid cracks caused by capillary forces, which one achieves by working under hypercritical conditions or by deactivating the silanol groups at the silica surface.

The term “colloidal silica sol” designates stable dispersions of amorphous silica colloids. One produces colloidal silica by careful neutralization of alkali silicate solutions with acids such as H_2SO_4 to pH values between 7 and 10 or by extracting alkalis with ion exchange – which also lowers the pH [4]. The final particle size ranges from 5 to 150 nm and depends on both the precipitation process (time, temperature, reactants) and the aftertreatment (temperature, colloid stabilization). The resulting sols are usually stabilized by alkalis or ammonia.

Precipitated silica is a nanoscale silica powder with a high surface area and an internal porosity that is obtained from colloidal silica sols, which are described above. The sols are washed and dried in drums or by spray drying. They are, for instance, applied to reinforce elastomers, e.g. as a substitute for carbon black in tires. The reinforcement is attributed to interactions via phase interfaces, and the high surface area of colloidal silica leads to larger effects. Precipitated silica is also used as additive in foodstuff in which it either prevents powders from caking or improves the flow characteristic of liquids. In some aspects it is comparable to pyrogenic silica, which can be made by flame hydrolysis of SiCl_4 .

The application of water glasses as fire-retarding materials was already mentioned by Fuchs [2]. If liquid water glasses are applied as coating or film, they dry to solid amorphous material containing residual water, which absorbs IR radiation and foams if heated to about 140°C . If a continuous layer of liquid water glass is carefully dried under controlled atmospheres on a flat surface, e.g. a window pane, it forms transparent amorphous solid sheets. Commercial types of these transparent materials contain organic additives (e.g. to prevent ice crystallization during cold weather) and are also used as transparent intumescent layers in fire-resistant glazings. Because dried potassium water glasses have lower water contents, sodium water glasses are the superior materials for this application.

Liquid water glasses can be spray-dried to yield alkali silicate powders with water contents of about 20 wt %. The powders dissolve very quickly in water and are used in detergents or in binders to supply reactive silica and alkalinity very fast.

5.2 Crystalline Materials: Zeolites and Crystalline Sodium Silicates

Liquid water glasses and mineralizers (e.g. sodium aluminate) can react under hydrothermal conditions to form zeolites. These framework aluminosilicates have holes filled with ions or molecules in their structure, which enable them to be used for ion exchange, absorption, or catalysis. Important products are water softeners and industrial catalysts.

Layered sodium silicates are applied as ion exchangers: their sodium ions exchange with metal cations. In the case of ion exchange with Mg^{2+} or Ca^{2+} , they act as water softeners or builders.

5.3 Binders

The solidification of water glass used as binder occurs via drying to a solid, reaction with atmospheric CO_2 , neutralization with an acid, or reaction with specific hardeners such as sodium or aluminum phosphates. Liquid water glasses as well as powder varieties (anhydrous or water containing alkali silicate materials) can be applied in binder formulations or as additive to other binders. The application for foundry sands is revived due to environmental reasons. New types of binders are alkali activated cements and geopolymers where the alkalinity of NaOH lyes or water glass accelerates the hydration reactions of aluminum silicates or of pozzolans. Potassium water glass is applied as binder in pigmented paints because it does not effloresce under ambient atmosphere [7]. Lithium water glasses are required when a higher chemical resistance of binders or paints or lower alkali contents is required. Quaternary ammonium containing water glasses can be used as binders [13] for higher temperatures since they contain no alkalis reacting as flux for acidic oxides.

6 Perspectives

Research and development on water glass concentrates on lowering both energy consumption and CO_2 output during production and the development of new and environmentally friendly products. On both counts, hydrothermal dissolution of silica has clear advantage. New applications like alkali activated binders, which may substitute at least partly ordinary Portland cements and introduce new features like higher temperature or chemical resistance, will also enhance the importance of water glass. On the scientific side, a better understanding of the structure of water glass with its balance between smaller

molecules and colloids and of the thermodynamics of the system will also be important for improving existing products and designing new ones.

Borosilicate Glasses

Randall E. Youngman

Science and Technology Division, Corning Incorporated, Corning, NY, USA

1 Introduction

Borosilicates have made a late showing in the four-millennia glass history. They appeared only in the nineteenth century when, with the burgeoning growth in optics and a concomitant need for better lenses, scientists like Michael Faraday (1791–1867), in England, and Ernst Abbe (1840–1905) and Otto Schott (1851–1935), in Germany, looked beyond the typical crown and flint glasses of their days. The old method of correcting optical aberration through multiple lenses with different optical properties was, for instance, cumbersome, expensive, and only marginally successful, especially with the growing demands from telescope and microscope technology. As Faraday explained in a series of lectures on his research to improve optical glasses [1], addition of boron oxide was a simple means to obtain more homogeneous glasses for better optical performance.

Abbe, who recognized this need, had the good fortune of engaging the mind of a young Otto Schott, who began to work on different glasses for these types of applications. In 1884, the Schott & Associates Glass Technology Laboratory in Jena began production of a series of new optical glasses containing boron oxide – the first commercial venture in which boron oxide was a significant component. Introduction of B_2O_3 did eventually solve the problem of chromatic aberration and led to a revolution in optical glass [2]. This event marked the first of a long series of commercial successes met by the new glass family, which was, for instance, quickly followed by the development of thermal shock-resistant glasses for lamps.

At the roots of this advancement was an unusual easiness to prepare homogeneous glasses and the possibility to obtain the very low coefficients of thermal expansion (CTE) needed to ensure resistance to thermal shocks caused by rapid changes in temperature. Hence, after a brief review of the main uses of borosilicate glasses, the main concern of this chapter will be to account in structural terms for such outstanding features. As established by pioneering work made by Weyl [3] and Abe [4] in the mid-twentieth century, the most important factor in this respect is the complex speciation of boron, which is either three- or fourfold coordinated with oxygen, as B(III) or B(IV) units, respectively, and varies with chemical composition, temperature, and pressure. Particular interest will thus be paid to these variations and also to the superstructural units associated with the different boron polyhedra. Emphasis will be placed on glasses in the sodium borosilicate ternary, which exhibits a large compositional region of glass formation and an extensive and well known immiscibility but also contains within it some of the most important commercial borosilicate glasses (Figure 1).

2 Borosilicate Applications

2.1 Early Products

Some of the first commercial borosilicate glass compositions offered by Schott & Associates Glass Technology Laboratory, later Jena Glass Works and now Schott AG, are listed in Table 1. The initial optical glass facilitated the development of microscopy in medicine and telescopic instruments for astronomy. After heat tolerance had been discovered by Schott in 1892, his *Jena Apparatus Glass*, which was in addition highly resistant to chemical attack, thus became widely adopted in

chemistry labs. In 1893, Schott found a new borosilicate glass that was insensitive to sudden changes in temperature. Since this material was “practically indestructible for incandescent lamp cylinders,” it became a huge

Figure 1 The $\text{Na}_2\text{O}\cdot\text{B}_2\text{O}_3\cdot\text{SiO}_2$ phase diagram, with estimated compositional limits of glass formation and large region of immiscibility (hatched area). Pyrex- and Vycor-related regions are denoted.

commercial success [5]. Prior to the development of this composition (Table 1), glasses used for this application had long been known for instability and loss of accuracy over time.

Shortly after Schott & Genossen commercialized borosilicate glasses, Corning Glass Works in the United States began to experiment with them, greatly facilitated by a “candid exchange of idea” between Jena and Corning [5]. Corning’s first product was for Fresnel-type lenses in railroad lanterns (high-temperature arc lamps), which solved a critical failure mechanism through thermal shock resistance. Soon after, a glass named Nonex (Corning nonexpansion glass) was introduced as a heat-resistant lantern-globe glass.

Borosilicate glasses, and perhaps the glass industry in general, were then significantly impacted by World War I, during which the United States and England were both at risk of losing critical supplies of high-quality optical glass made in Germany. This threat ultimately concerned a larger scientific community in that chemical- and heat-resistant laboratory glassware, made from a Schott & Genossen borosilicate glass composition, was also in short supply. By 1915, Corning had solved this particular issue and made a historical contribution to glass science by inventing and commercializing Pyrex [6],

originally called Pyright but changed to rhyme with the aforementioned Nonex. Along with Pyrex, Schott's Duran and other products developed over the past century are arguably the best known and commercially successful examples from the borosilicate glass family. To this day, they have been used in scientific lab- and kitchenware, thermometers, high-temperature appliances, telescope blanks, X-ray tubes, and many other common products. Hence, what began as a solution to Abbe's request for better optical glass spawned an entire industry as well as numerous intellectual studies of glass physics, chemistry, and processing.

Even a century after its invention, however, a material as ubiquitous as Pyrex remains studied for its structure and properties to improve its understanding [7]. At least from the network-forming cation (boron and silicon) perspective, this structure is readily determined with nuclear magnetic resonance (NMR) spectroscopy (Chapter 1.2). The ^{11}B NMR spectrum (Figure 2) in particular allows for determination of the fraction of tetrahedrally coordinated boron (N_4) and in addition provides evidence for a rich short-range structure composed of multiple B(III) and B(IV) environments. The challenge thus is to make sense of such information to control and optimize glass properties – the next frontier in efficient discovery, development, and commercialization of new borosilicate glass compositions.

2.2 Modern Materials

Resulting from a better understanding of glass leaching and phase separation, another commercial milestone was the development of Vycor glass in 1939 by H. Hood. Phase separation in $\text{Na}_2\text{O} \cdot \text{B}_2\text{O}_3 \cdot \text{SiO}_2$ glasses can be quite extensive (Figure 1). It generally results in a boron- and sodium-rich phase, which is readily dissolved by mineral

acids and leaves behind a primarily silica-rich glass. The porous microstructure can be coarsened with thermal treatment, allowing for a wide range of porosities. Although this porous glass has found many applications, for example, as filters and membranes with pore sizes ranging from 20 to 220 Å, Vycor is more commonly used after heat treatment and consolidation of the porous silica-rich glass: a glass article can thus be generated from an easily melted and shaped alkali borosilicate glass, which, after controlled phase separation and leaching, collapses into a homogeneous glass similar in composition to pure silica. Such an approach circumvents more costly and challenging processing of silica glass into complex shapes. These dense Vycor articles exhibit very low CTE and are thus especially useful in high-temperature applications (e.g. crucibles).

Originally developed in 1940 without incorporation of boron oxide, E-glass was modified in the 1950s to the standard borosilicate composition (Table 1) by Owens Corning Fiberglass Corporation. This product represented another significant milestone in the commercial history of borosilicate compositions, as the market for this type of borosilicate glass has been extensive and long lasting. These fibers have been used primarily as insulation and reinforcing materials (Chapters 1.5 and 9.3), accounting for up to 99% of the commercial fiberglass market [8]. Much of the subsequent scientific and technical work on E-glass fibers has focused on tailoring mechanical properties, increasing their chemical durability, and finding environmentally and energy friendly compositions (Chapter 1.5).

A rather different but significant area of interest/application for borosilicate glasses deals with nuclear waste storage (Chapter 9.10). Vitrification of such waste in borosilicate glass hosts is being used in a number of countries on a fairly large industrial scale. Some estimates suggest that more than 90% of the highly radioactive, heat-producing nuclides from spent fuel are immobilized in borosilicate matrices. The principal concerns and, therefore, research interests pertain to glass corrosion and the ability to store safely these wastes in vitreous form. The better part of five decades of research has focused on aqueous corrosion of these glasses and potential mobilization of the hazardous material. Two fundamental aspects of borosilicate glass corrosion continue to be the initial water diffusion and ion exchange with the borosilicate glasses, as well as network hydrolysis and dissolution (Chapter 5.12). Solution saturation and reprecipitation of crystalline and amorphous materials further complicate the understanding and use of borosilicate glasses in this particular application. Current knowledge and usage include standardized compositions, such as the International Simple Glass (ISG) in Table 1, allowing for broader and more comprehensive research into

Figure 2 Coexistence of B(III) and B(IV) in Pyrex glass as clearly revealed by ^{11}B MAS NMR spectra (magnetic field of 11.7 T) [7]. Deconvoluted peaks corresponding to multiple B(III) and B(IV) sites are denoted by dashed lines.

borosilicate glasses for nuclear waste immobilization by many different international groups [9].

At this moment, however, the current commercial leader in borosilicate glass products is their use as liquid crystal display (LCD) substrate glasses and as protective cover glasses and touch screens in consumer electronic applications (Chapter 6.9). As shown by some representative examples in Table 1, the majority of these high-tech glasses are based on borosilicates in which additional network modifiers and formers are introduced along with other additives to tailor their properties for specific applications. Corning Code 1737 (Table 1) was developed early in the commercialization of LCD, serving as an alkali-free substrate material for this technology. Today, LCD substrate panels are made with a variety of different borosilicate and related glass compositions and represent one of the largest markets for thin glass sheets (Chapter 6.9). A related new business, with very different material requirements, concerns glasses for handheld consumer electronics such as Corning® Gorilla® Glass, SCHOTT Xensation®, and Asahi Dragontrail® used for protecting covers that are highly engineered by chemical strengthening to survive a variety of possible damaging events (Chapter 3.12).

Although most of the latter products are now made from aluminosilicate glasses, sometimes without the incorporation of boron oxide, some of the early work on chemical strengthening included borosilicate compositions. The chemical tempering, or ion exchange of glass, originally demonstrated with Ag^+ diffusion by Schulze [10] and then with alkali exchange by two groups, Kistler [11] and Acloque and Tochon [12], requires incorporation of some mobile (i.e. exchangeable) species in the glass (Chapter 3.12). Exchange of a smaller cation (e.g. Na^+) with a larger cation (K^+) leads to surface compression and a more damage-resistant glass surface. In general, addition of Al_2O_3 leads to favorable properties such as density and formability, including suppression of miscibility gaps, so boroaluminosilicates tend to be the more commonly developed and utilized commercial glasses for these modern technological applications.

3 Vycor: A Composition–Structure Case Study

Glasses form from pure silica to pure boron oxide in the binary B_2O_3 – SiO_2 system. They are generally well characterized in terms of network structure and other important aspects, including phase separation [13–15]. The latter results from metastable immiscibility and extends as a ternary immiscibility dome in sodium borosilicates (Figure 1). Introduction of small quantities of high field

strength cations (e.g. Li^+ and Ca^{2+}) accentuates the phase separation originally present in binary borosilicate glasses [16].

In early studies, X-ray scattering was used to determine the first sharp diffraction peak, correlating with an average cation–oxygen distance that increases from zero to ~45 mol % silica and is then constant at higher SiO_2 contents. A recent study investigated the contributions of superstructural units (e.g. boroxol rings) to binary borosilicate vibrational density of states and the corresponding impact of this type of structure on thermal properties [17]. In spite of an apparent lack of significant commercial interest in these binary glasses at the present time, some of these compositions have been used in optical fibers and anticorrosive coatings. Sol–gel processing of binary B_2O_3 – SiO_2 glasses has been one particular area of recent study, indicating that truly homogeneous glasses in this binary system can be achieved [18].

That ready vitrifiability frequently coexists in borosilicate glasses with immiscibility and phase separation has intrigued and often frustrated researchers for the past many decades. Perhaps the simplest and most illustrative example is that of ternary alkali borosilicates such as those of the Na_2O – B_2O_3 – SiO_2 system (Figure 1), which includes some of the more famous commercial compositions. As illustrated by Vycor glass, the existence of a large liquid immiscibility dome is not necessarily detrimental, but it can complicate the fabrication process. Hence, one of the interesting and currently relevant questions in such systems is a precise understanding of the microstructure of these phase-separated glasses in terms of either spinodal or nucleation–growth coalescence-type mechanisms (Chapter 5.2).

A deeper understanding of glass structure at both short and intermediate ranges may also aid in understanding phase separation. For example, ^{11}B MAS NMR spectra of Vycor (Figure 3) give insight into the boron atomic environment in the material as it is processed. The spectrum of a heat-treated product, which resembles that of

Figure 3 Variations of boron speciation upon processing of Vycor glass shown by ^{11}B MAS NMR spectra (magnetic field of 11.7 T).

the as-made glass but with enhanced phase separation, shows a large fraction, N_4 , of boron in B(IV) groups of about 30 %, reflecting the strong association between boron and charge-compensating sodium. Upon chemical leaching of this heat-treated glass, one obtains porous Vycor whose composition and structure have been significantly altered through elimination of the poorly durable sodium borate phase.

The ^{11}B MAS NMR data actually indicate that the residual boron is found as B(III) units (Figure 3), consistent with the fact that the porous Vycor is a SiO_2 -rich phase containing only a small fraction of B(III) and essentially no modifier. In other words, this glass is a binary borosilicate whose ^{29}Si NMR spectrum (not shown) is mainly composed of Q^4 tetrahedra along with Q^2 and Q^3 silicate groups associated with surface silanol groups, which can be substantially reduced, or even eliminated, with further heat treatment and consolidation into a dense glass. As a simple conclusion, one can thus state that a technique such as NMR depicts the main steps involved in the formation of porous Vycor glass in such a way as to enable researchers to design and optimize the phase separation and leaching processes and, thus, to control accurately the composition, microstructure, and properties of the material.

4 Structural Aspects

4.1 Fourfold Coordinated Boron

The relatively simple $\text{Na}_2\text{O}-\text{B}_2\text{O}_3-\text{SiO}_2$ glasses are representative of many borosilicates. Their network structures have been examined with a wide variety of tools (NMR, Raman, neutron scattering, X-ray diffraction, etc.), which has resulted in structural models accounting for three- and fourfold coordinated boron or nonbridging

Figure 4 Compositional dependence of fourfold coordinated boron in alkali borosilicate glasses according to the model of Dell et al. [19]. Fraction of tetrahedral boron, N_4 , plotted as a function of $R = \text{R}_2\text{O}:\text{B}_2\text{O}_3$, dashed lines representing the impact of $K = \text{SiO}_2:\text{B}_2\text{O}_3$ on these values.

oxygen (NBO) on silicon (Chapters 2.1 and 2.4), as well as for properties of these glasses, including the contributions of B(IV) groups and overall network polymerization toward lowering thermal expansion. A very influential model was based by Dell et al. [19] on pioneering ^{11}B NMR work to predict the fraction of B(IV) as a function of both modifier content and $\text{SiO}_2:\text{B}_2\text{O}_3$ ratio (Figure 4). It assumes that each sodium added induces the conversion of a BO_3 trigonal unit into a BO_4 tetrahedron, consistent with the fact that B_2O_3 -rich glasses typically contain a significant fraction of both polyhedra as indicated by the relative ^{11}B peak intensities in NMR spectra (Figure 5). For $x = 60$ in Figure 5, the observed N_4 value, slightly higher than 0.3, agrees with the model predictions

Figure 5 Effect of Si-B substitution on boron speciation in $17 \text{ Na}_2\text{O} \cdot x \text{ B}_2\text{O}_3 \cdot (83-x) \text{ SiO}_2$ glasses on ^{11}B MAS NMR spectra (11.7 T). For each composition, the N_4 value is given to the right in the same order as for x . Resonances from B(III) and B(IV) groups are denoted, along with the peak positions for two distinct types of B(IV) environments (dashed lines) [20].

[19] made from the parameters $R = 0.3$ and $K = 0.3$ characterizing this particular composition (Figure 4). A similar agreement for N_4 of about 0.77 is found for the $x = 15$ glass with the predictions made for $R = 1.33$ and $K = 4.33$. Even though it is nearly 40 years old, the Dell et al. model thus remains valid for a variety of borosilicate glasses, especially at modest R and K values. The trends in N_4 predicted by such a model are also consistent with physical property trends, in that an important characteristic of these glasses, namely, the thermal expansion, is controlled by the degree of polymerization, which depends directly on the concentrations of B(IV) and NBO. The competition between these two structural features upon addition of modifier oxide opposes a tetrahedrally coordinated network-forming cation (e.g. B(IV)) to a depolymerized silicate group having fewer than four covalent linkages to other network formers, thus involving a large impact on local topology of the glass.

For larger values of these ratios (e.g. $R > 1$ and $K > 8$), however, the model predicts N_4 values of 100%, which would mean that all boron atoms are in fourfold coordination. But actual ^{11}B NMR-derived N_4 values are always lower than 100% because these high modifier (Na_2O) concentrations eventually lead to the creation of NBO on silicon atoms instead of additional B(IV) groups. The competing role of charge-balancing cation and network modifier exhibited by Na^+ is even more complicated for other modifying oxides, especially for the alkaline earth cations, for which multinuclear NMR data have shown that cation field strength dictates the extent of B(IV) charge balancing by the modifier [21, 22]. As a result of these changes in network structure with different modifiers, the physical properties of such borosilicate glasses are also impacted, with fewer B(IV) groups and a larger number of NBO leading to network depolymerization, a drop in T_g , and a negative correlation between CTE and boron speciation. Although new models

have been designed to allow for a more random distribution of modifiers between the borate and silicate groups [21, 23], they do not predict accurately enough the boron coordination, especially when additional network-forming cations (e.g. Al_2O_3 or P_2O_5) are added. Further characterization and model development are thus necessary to understand better the short-range structure in these glasses.

4.2 Silicon–Boron Mixing

The manner in which network-forming silicon and boron mix can also be investigated by ^{11}B MAS NMR spectroscopy. For glasses with similar amounts of Na_2O (Figure 6), the impact of $\text{SiO}_2 : \text{B}_2\text{O}_3$ ratio is reflected by the measured N_4 fraction. As predicted by structural models (e.g. Figure 4), the coordination of boron is mainly determined by the $\text{R}_2\text{O} : \text{B}_2\text{O}_3$ and $\text{SiO}_2 : \text{B}_2\text{O}_3$ ratios. Compositions with high K values, such as that of Figure 6b, allow for much larger N_4 values caused by mixing of the silicate and borate polyhedra, driven perhaps by relaxation of B(IV) avoidance (i.e. avoidance of B(IV)–O–B(IV) linkages) that is important for glasses containing higher amounts of B_2O_3 (e.g. lower K values).

Mixing of silicate and borate polyhedra is not necessarily ideal, however, so some B(IV)–O–B linkages are evident from the appearance of a second B(IV) resonance in these glasses. One resonance at approximately -1.4 ppm (Figure 6b) is assigned to B(IV) with four silicon next-nearest neighbors (NNN). Owing to the low SiO_2 content of this particular glass, some of the B(IV) are surrounded by fewer Si NNN, the difference being at least one B NNN. The peak at $+0.2$ ppm in Figure 6b is B(IV) with 3Si and 1B NNN. As shown for Pyrex in Figure 2, multiple B(IV) peaks resulting from ordering between boron and silicon are important and common features for borosilicate glasses. The relative population,

Figure 6 ^{11}B MAS NMR spectra for (a) a boron-rich glass with composition $17 \text{ Na}_2\text{O} \cdot 60 \text{ B}_2\text{O}_3 \cdot 23 \text{ SiO}_2$ measured at 11.7 T [20] and (b) a silica-rich glass ($20.4 \text{ Na}_2\text{O} \cdot 21.7 \text{ B}_2\text{O}_3 \cdot 57.8 \text{ SiO}_2$) measured at 16.4 T [24]. Solid lines are the experimental NMR data, and dashed lines represent simulations of the various B(III) and B(IV) components, as labeled.

or extent of mixing between B and Si, is very sensitive to glass composition because B(IV)(4Si) is predominant in silica-rich glasses, in contrast to glasses having higher concentrations of B₂O₃, where more B(IV)–O–B linkages (e.g. B(IV)(3Si,1B) units) are common, as shown by the changes in B(IV) peak position with varying *K* in Figure 5.

From a practical standpoint, mixing of B³⁺ and Si⁴⁺ in the anionic framework, made possible by association of boron with charge-compensating cations such as alkali ions, has important consequences. When added to silicates, B₂O₃ causes large freezing point depressions because of its very low melting temperature of 712 K, an effect that is still enhanced by the entropy of Si–B mixing. This is the reason why homogeneous glasses are obtained at lower temperatures for borosilicates than for silicates. The effect is similar to that yielded by addition of alkali oxides to silicates, but it has the important advantage of not affecting significantly the polymerization state of the material and, thus, not degrading its stability.

4.3 Superstructural Units

Another widely debated topic is the occurrence of superstructural units in the network. Six-membered rings composed of B(III) and B(IV) polyhedra (and their associated bridging oxygens) are ubiquitous in alkali borate glasses, as shown by NMR and Raman spectroscopies or other structural probes. In borosilicate glasses, some of these ring structures are thought to form through incorporation of both silicate and borate polyhedra, as in the minerals danburite [CaB₂(SiO₄)₂] and reedmergerite [NaBSi₃O₈]. As characterized by such well-defined superstructural geometries, this type of intermediate-range structure is apparently unique to borate and borosilicate glass families. Its identification is particularly effective with ¹¹B NMR and Raman spectroscopies.

As seen for Pyrex (Figure 2) and other borosilicate glasses (e.g. Figure 6), the ¹¹B MAS NMR spectra contain considerably more information than simply on boron coordination numbers. As discussed for B(IV) peaks, the presence of multiple B(III) resonances is reflective of multiple structural environments involving BO₃ polyhedra. This feature has been studied not only with ¹¹B MAS NMR but also with ¹¹B dynamic-angle spinning (DAS), double-rotation (DOR), and multiple-quantum magic-angle spinning (MQMAS) NMR spectroscopy. The fits made to the spectra (not shown) generally yield two distinct B(III) species having similar quadrupolar coupling parameters, but differing significantly in their isotropic chemical shifts. This chemical shielding difference of 3–4 ppm was first measured in glassy B₂O₃ and attributed to boroxol ring and non-ring B(III) units [25]. The multiple B(III) peaks detected in ¹¹B NMR

experiments, like in the examples herein, have been consistently interpreted in terms of ring and non-ring B(III) species: the ring peak represents B(III) units in boroxol and modified rings (e.g. tetraborate, triborate, danburite, etc.), whereas the non-ring B(III) environment includes those of BO₃ polyhedra that exist outside of these well-defined superstructural units.

Over broad compositional ranges, the presence of ring-type B(III) indicates that the borosilicate glass network is characterized by a surprising amount of short- and intermediate-range order. These features have important implications for network topology and the nature of the network-forming species that control the physical and mechanical properties of the glass. One of the ongoing challenges in this field is the identification and absolute confirmation of different network polyhedra and ring structures in highly modified borosilicate glasses. For those glasses containing NBO, especially when these are bonded to boron atoms, the complexity in their NMR and vibrational spectra is significantly increased. In addition to the possibility of ring and non-ring B(III) units, as well as of multiple types of B(IV) polyhedra based on mixing between B and Si units, the presence of metaborate units (B(III) with a single NBO) would appear as yet another B(III) resonance in the ¹¹B NMR data. The combination of multiple spectroscopies, and possibly new advances in NMR methodology, should yield better and more precise descriptions of these complex glass structures.

4.4 From NMR to Integrated Studies

To begin with oxygen, other nuclei amenable to NMR experiments are incorporated in borosilicate glasses. In particular, ¹⁷O NMR has been used to understand the network connectivity between borate and silicate groups, lending in this way support to the characterization of phase separation in binary B₂O₃–SiO₂ glasses and to a detailed understanding of topological disorder and phase separation in multicomponent borosilicates [14, 26]. Additional NMR studies have dealt with ²³Na, ⁶Li, ⁷Li, ¹³³Cs, ⁴³Ca, and ²⁵Mg modifier cations, allowing researchers to understand the local environment of these components, as well as the impact of such modifiers on the network structure and properties of borosilicates of academic or commercial interest. In this respect, Na⁺ and Li⁺ are two modifiers of significant interest in model systems and in the development of better structure–property relationships that are important in commercial glasses utilizing ion exchange for mechanical toughening (Chapter 3.12).

Although NMR has become one of the mainstream characterization tools for network structure, other spectroscopies and computational methodologies have been

extensively developed to learn about the physics and chemistry of borosilicate glasses. Vibrational spectroscopies, for example, continue to play a key role in understanding the network structure of borosilicate glasses. Starting with the seminal work of Konijnendijk [27], Raman spectroscopy has been instrumental in developing and contrasting structural models for borosilicates with those designed for borate and silicate glass families, for instance, with respect to danburite and reedmergnerite superstructural units [28, 29].

Whereas knowledge of the structure of borosilicate glasses has been significantly advanced over the past 50+ years, a precise description of short- and intermediate-range network structure, including mixing of the two glass-forming oxides, continues to be a challenge in both experimental and theoretical approaches. Some of the more recent advances in this arena involve a combination of experimental and modeling studies whereby empirical models are for instance complemented by theoretical calculations of NMR spectra or molecular dynamics (MD) simulations [30]. Purely computational approaches also are common and have yielded potentially important insight into these issues. As advanced during the last past decades, MD simulations have been validated in terms of reproducing boron NMR data (i.e. N_4 values) and other structural details obtained by spectroscopic investigations (Chapter 2.8).

4.5 The Impact of Al_2O_3

In addition to these studies on relatively simple glasses, much experimental work has been devoted to the effects of additional glass formers on structure and properties. As a crucial component of new products, Al_2O_3 has been extensively investigated because the presence of such a third glass former complicates the interactions between modifiers and both B_2O_3 and SiO_2 . The ratio of modifier to Al_2O_3 in these boroaluminosilicates actually controls many properties, including density and T_g . These features and the concomitant changes in the glass structure have been elucidated primarily by means of multinuclear NMR techniques [31, 32].

In fact, addition of Al_2O_3 also requires charge-compensating cations to stabilize Al in tetrahedral coordination, which lowers the fraction of network-modifying cations. As a consequence, the NBO content decreases and, if the glass is highly modified, also reduces the N_4 fraction. The resulting glass network may exhibit more connectivity, in particular if Al_2O_3 addition reduces or eliminates NBO on both boron and silicon. In glasses containing few modifiers, for example, below the Dell et al. critical R^* value [19], then boron is typically converted from tetrahedral units back to trigonal species.

This transformation has of course a large impact on glass properties.

Current understanding and related empirical models of boroaluminosilicate glasses often consider simplified interactions between modifiers and network formers by assuming that Al_2O_3 is preferentially stabilized in AlO_4 units, with any “excess” modifier then made available for other structural changes. This assumption appears to hold generally for a great many systems, but may not be exact, so models based on this view would also be inaccurate. Recent work on boroaluminosilicates conducted by several prominent research groups does indeed show that all Al is not necessarily in fourfold coordination in charge-balanced compositions. The presence of a non-zero AlO_5 population, which may also be sensitive to fictive temperature and compression of the glass, suggests a more complicated interaction between network modifiers and formers in these multicomponent borosilicate glasses. This topic thus continues to be an active area of research. Advances in both experimental and computational study will result in a better structural understanding of glass formation and properties, perhaps also leading to additional commercial and scientific opportunities.

5 Temperature and Pressure Variations of Network Structure

5.1 Temperature vs. Entropy

With rising temperature, the structure of a melt necessarily varies so as to ensure an increase in configurational entropy. In borosilicates, changes in boron speciation are a simple way to fulfill at least partially this requirement. Particularly in highly modified glasses [21], one can actually shift markedly the equilibrium between B(IV) and NBOs by varying the quenching rate to freeze the short-range structure at different fictive temperatures (Figure 7). Although the largest impact of T_f is on boron speciation, a modification of the line shape apparent on closer examination of B(IV) peaks (Figure 7) indicates more complicated changes in the network structure. The quenched glass has at least two types of B(IV) that are not well resolved in the 11.7 T spectra but are nonetheless indicated by the noticeable asymmetry of the B(IV) peak. Annealing induces a slight increase of the relative intensity at the upfield (more negative shift) side of the peak, which one would assign to B(IV) surrounded by 4 Si NNN. If this intensity change is meaningful (e.g. reproducible and outside of the measurement uncertainty), then such data indicate that a change in thermal history for this glass causes an overall increase in N_4 .

Figure 7 Increase in the B(IV) fraction in a sodium borosilicate glass upon annealing of a quenched glass, shown by a comparison of ^{11}B MAS NMR spectra (11.7 T) [33].

much of that change not affecting equally all B(IV), but mainly those surrounded by 4 Si.

A closely related area of significant interest, but rather challenging to study with traditional characterization tools like NMR, is the structure of borosilicate melts and supercooled liquids. Most of the commercially relevant borosilicate glasses are processed from melts, so it stands to reason that a deeper knowledge of glassmelt properties and structure would be immensely beneficial. Some *in situ* methodologies do exist and have been used to characterize glassmelts, but even high-temperature NMR and other spectroscopies are difficult to implement and are generally restricted to specialized laboratories. One area of growing utility and popularity relates to optical interrogation of glassmelts, involving small furnaces, laser heating, and laser heating with aerodynamic levitation. These methods provide a means by which to use Raman and Brillouin light scattering, neutron diffraction, and high-energy X-ray scattering to study glassmelt chemistry and physics (Chapter 2.2). In a recent neutron diffraction examination of boron coordination in borosilicate melts, dramatic decreases in N_4 on melting two borosilicate glasses were, for instance, observed, such structural insight having then

been discussed in the context of the structural underpinnings of melt viscosity [34].

5.2 Pressure vs. Volume

With increasing pressure, the structure of a melt necessarily becomes more compact to ensure the thermodynamically required density increase. For obvious reasons, the effects have been well documented for glasses of geochemical interest whose network structure has indeed been found sensitive to pressure. Hence, it should not come as a surprise that these investigations have recently been extended to borosilicate glasses. One particularly recent study, using NMR to understand changes in glass structure, but, more importantly, to correlate pressure and short-range structure with glass properties, indicates that certain changes with modest pressure may be irreversible [35]. To illustrate better the changes in glass structure with pressure, ^{11}B MAS NMR spectra have been obtained on two borosilicate glasses before and after high-temperature compression at T_g and 1 GPa. In both glasses (Figure 8), the impact of compression on boron speciation is an overall increase in N_4 , much like the changes in structure with thermal history alone.

In addition to N_4 variations, a preferential change in the type of B(IV) is indicated for the sodium borosilicate glass (Figure 8a), as found for similar glasses having different thermal histories. Here, the peaks assigned to B(IV) with 3 Si, 1 B, and 4 Si NNN, B(IV)(3Si1B), and B(IV)(4Si), respectively, change differently upon compression, with a larger increase in the B(IV)(4Si) concentration. Closer examination of the B(III) region of these spectra gives additional insight into related changes in ring and non-ring B(III) peaks with compression – something that is currently the subject of a combined NMR and Raman study of borosilicate glasses under permanent densification. One of the other structural responses to this high-temperature compression relates to the modifier environment. As mentioned earlier, NMR studies of ^{23}Na (or

Figure 8 Effects of permanent densification on the boron speciation of two borosilicate glasses, as shown by the differences between the ^{11}B MAS NMR spectra (16.4 T) recorded for the as-made glasses (solid curves) and compressed samples at T_g and 1 GPa (dashed curves). (a) 20.4 Na₂O·21.7 B₂O₃·57.8 SiO₂ [24]. (b) 15.0 Na₂O·10.1 CaO·16.5 B₂O₃·58.4 SiO₂ [36].

other modifiers) allow one to follow changes in the local environment of these cations as glasses are densified. Many NMR studies have shown a clear increase in chemical shift of ^{23}Na for glasses densified by compression either at room or at elevated temperatures. Most of these data have been interpreted as a general reduction of the average Na—O distance in the densified glasses and not as a change in the coordination number of the alkali. Further understanding of both the glass network and the modifier environments, using advanced experimental and computational methodologies, is necessary to describe fully densification of borosilicates under high pressure and possibly during mechanical damage induced by nano- and micro-indentation.

6 Perspectives

In spite of almost two centuries of study, borosilicate glasses remain intriguing materials whose incredible commercial success justifies the widespread research efforts made to characterize them better and improve their structure–property relationships. Accurate determinations of glass structure across several length scales (short and intermediate range) will continue to drive new applications as it will be difficult to optimize compositional and processing variables, including temperature and pressure, without this information.

The next wave of innovation is actually underway: it is the development of ultra-strong glasses through better characterization of bulk and surface structure and properties [37]. Of particular importance in this respect are the details of flaw generation, crack growth, and overall glass durability and, in turn, the impact of these phenomena on glass structure and properties [38]. Applications of borosilicate glasses are also growing into new scientific and commercial areas, for example, in glass/polymer laminates or in biological uses. Hence, the surfaces of these materials become critical in their applications, driving the need for enhanced understanding and control of surface chemistry and properties, as well as of glass dissolution mechanisms.

In all these respects theoretical simulations will also be valuable. The interatomic potentials needed in MD simulations have thus been improved to yield correct structures and properties over wide ranges of composition. But the main difficulties remaining to be overcome concern the temperature sensitivity of cation coordination and the unrealistically high quench rates currently possible.

Advances in experimental and computational methodologies to understand and control better phase separation in borosilicate glasses may also lead to new and improved compositions. Even today, the development

of new NMR and transmission electron microscopy (TEM) capabilities have increased our ability to discern phase separation in glasses, which either account for or aid in understanding associated physical properties, as well as serve to understand better nucleation and crystallization in glasses.

Finally, many challenging problems in glass science will benefit from the study of model borosilicate systems. A deeper understanding of the glass transition, intermediate-range structure, phase separation and crystallization processes, impact of temperature and pressure on glass structure and properties, etc. is continually achieved through work on borosilicate glasses. Progress in new and advanced simulation approaches and experimental capabilities will also lead to an improved understanding of these important aspects of glass science.

Acknowledgments

This contribution has been influenced greatly by a large community of glass and characterization scientists at Corning Incorporated. In particular, collaborations with J. Mauro (Corning, Pennsylvania State University), M. Smedskjaer and Y. Yue (Aalborg University), S. Sen (University of California at Davis), and R. Dieckmann (Cornell University) have resulted in new and exciting understanding of borosilicate glasses. Thanks are also due to H. Yamasaki (NEG) for data communication.

Glass for Pharmaceutical Use

Daniele Zuccato¹ and Emanuel Guadagnino²¹ Stevanato Group, Piombino Dese, Italy² European Pharmacopeia Expert, Italian Delegate, Venezia, Italy

1 Introduction

One of its properties that originally made glass a highly prized material was its inertness with respect to liquids and other substances that it could contain (Chapter 10.2). The small vials for perfumes and unguents made as soon as bulk glass was produced in the late Bronze Age are a clear testimony of this ancient recognition. When it became common in the eighteenth century, the use of glass that for the storage of dry and liquid pharmaceuticals was thus the continuation of an extremely old tradition. Even though it has since then been replaced by plastics or other materials in a great many applications, glass has kept fundamental advantages in terms of chemical inertness, lack of porosity, shapability, transparency, coloration, or possibility of high-temperature sterilization. As a result, the use of glass in pharmacy keeps increasing, especially for new applications such as pre-filled syringes, which are the primary way for delivering new high-technology drugs.

The purpose of this chapter thus is to review the main features relevant to the use of glass in pharmacy. The pharmacopeial requirements for containers are first considered and a definition of the most common glass types provided. The current glass-tubing production processes are then presented, as well as the conversion steps to obtain containers from glass tubes. Next the factors affecting the mechanical resistance of the containers are briefly examined with a particular focus on the effects of glass forming and handling on the packaging performances. The chemical resistance of glass has important implications for the storage of pharmaceuticals. Hence,

possibly significant interactions between the container internal surface and the enclosed therapeutic agents are reviewed, with some considerations from the perspective of glass manufacturers. An account on the current internal and external treatments to improve the chemical and mechanical performances of the containers is provided. Finally, the chapter will examine some high-technology perspectives on the future of glass containers for parenteral uses (i.e. subcutaneous or intravenous injections), focusing on innovative solutions aiming at improving the patients' quality of life.

2 Glass Products and Types

Typical containers for pharmaceutical use are ampoules, vials, syringes, and cartridges (Figure 1):

- *Ampoules* remain the less expensive products available on the market. Their use keeps slightly increasing worldwide in that a growth in China, Japan, and other Asian countries compensates for a decrease in Western Europe and North America.
- *Vials* show a constant increase, growing in all markets because of their universal acceptance by end users and pharmaceutical companies. Such an increase is tightly connected to a quality improvement in terms of increasing output, lower rejection rates, and decreasing cosmetic defects.
- A high growth is shown by *cartridges* in all applications, whether dental, biotechnological, and insulin related. In the last case the so-called pen applications for self-administration are key success factors, but the highest quality is then requested in terms of cosmetic defects and dimensional tolerances because of the high cost of such drugs and the need to guarantee a very precise dosage.

Reviewers: P. Mascheroni, Helmholtz Center for Infection Research, Braunschweig, Germany
F. Nicoletti, International Commission on Glass and Stevanato Group, Piombino Dese, Italy

Figure 1 Different glass container types: ampoule, vial, syringe, and cartridge from left to right.

- The high growth of *syringes* production is driven by prefilling. Thanks to their ease of use and dosage accuracy, these containers are already the primary packaging of choice for many healthcare users. Their major markets are either key therapies that include vaccines, low-molecular-weight heparins, biotech products or applications in combination with auto-injectors.

The use of glass for pharmaceutical preparations is ruled by pharmacopeia authorities. The European [1] and US pharmacopeias [2] acknowledge two different types of glasses, namely, *neutral borosilicate* and *soda lime*, and three different types of glass containers according to a well-established classification based on their hydrolytic resistance (Chapter 5.1). In order of decreasing cost, these are the following:

- *Type I glass containers* are made of neutral borosilicate glass, which have intrinsically a high hydrolytic resistance. These containers can thus be used for any purpose.
- *Type II glass containers* are usually made of soda-lime glass. Being subject to alteration by contact with aqueous solutions (Chapter 5.11), they can be internally treated over a thickness of about 0.5 μm to acquire a hydrolytic resistance equivalent to that of type I glass. These containers are suitable for acidic and neutral aqueous preparations for parenteral use.
- *Type III glass containers* are made of untreated soda-lime glass. Owing to their moderate chemical resistance, they are suitable in parenteral use only for nonaqueous preparations.

The general segmentation of the overall 35–45 billion glass containers produced yearly would indicate a large preponderance of ampoules (Figure 2). In terms of value

Figure 2 Distribution of pharmaceutical glass containers in terms of production volume.

Figure 3 Segmentation of the value (€) of the different container types, year 2017.

as expressed in euros (Figure 3), syringes and special devices generate in contrast the highest revenues, whereas ampoules provide the lowest, clearly illustrating the value added in the highly engineering part of the production.

3 Production of Pharmaceutical Glasses and Containers

Pharmaceutical containers are produced from type I and III glasses in the compositional ranges shown in Table 1. Coefficients of thermal expansion (CTE) range from 49×10^{-7} to $55 \times 10^{-7} \text{ K}^{-1}$ for clear glass and from 52×10^{-7} to $54 \times 10^{-7} \text{ K}^{-1}$ for amber glass (Chapter 6.2), whereas the working points lie between 1145 and 1165 $^{\circ}\text{C}$ for the former and between 1120 and 1165 $^{\circ}\text{C}$ for the latter, with annealing temperatures ranging from 535 to 575 $^{\circ}\text{C}$. Type I clear glasses includes also high-borosilicate glasses (the

so-called Exp.33 glasses), thus having higher boron and silica contents and lower alkali contents with a CTE of about $33 \times 10^{-7} \text{ K}^{-1}$. Of course, knowledge of these parameters is of primary importance for the manufacturing process.

3.1 Glass-Tubing Production

Glass tubes or canes are produced with either the Danner or the Vello process (Figure 4). In both processes the starting point is the furnace where raw materials of the glass batch are melted. As a continuous flow, the melt then is shaped as a tube [3]. After these steps the tubing is gauged, classified for use, and cut into the desired lengths.

Named after Edward Danner who was working in the 1910s at Libbey Glass (Toledo, USA), the former can make tubing of 1.6–66.5 mm in diameter and rods of 2.0–20 mm in diameter at drawing rates of up to about 7 m/s for the smaller sizes and with a maximum daily production of up to 40 tons for the largest diameters. With this process, an angled rotating sleeve allows the introduction of air to inflate the tubing. The glass flows at about 1200 °C from the forehearth on a rotating, hollow,

water-cooled mandrel. The outside diameter and the thickness of the finished tubing are then controlled at about 900 °C by the flow of inflating air together with the drawing and rotation speeds and the inclination of the mandrel, which is usually 15–20° from the horizontal.

Named after Leopoldo Sanchez-Vello, the second process was first patented in 1929 in France. In this case, the glass flows from a forehearth into a reservoir in which a hollow bell-shaped mandrel rotates in a ring that allows the glass to flow via the annular space to give a continuously emerging tube. Air is fed via the end of the bell where there is a hollow tip. The dimensions of the tubing are controlled by the rate of draw, the clearance between the bell and the ring, the rate of drawoff, and the pressure of the blowing air. Production rates can be twice as high as with the Danner process, so the size of the drawing line is also much longer to reach from 100 to 140 m.

3.2 Container Production from Tubing

Glass vials can alternatively be produced by blow molding of glass gobs as described in Chapter 1.5. Only the glass-tubing converting technology will thus need to be described here. From tubing to vials the forming process with vertical converting machines is shown in Figure 5 in a clockwise sequence: (i) opening of tubing bottom, (ii) forming of the vial shoulder, (iii) forming of the vial mouth, (iv) cutting of the tubing, and (v) forming of another vial bottom. The whole forming process of vials and ampoules is realized by gas burners, whereas it also includes a thermal shock cutting phase for cartridges and syringes.

These steps are of course part of the production procedure in a long production line (Figure 6) beginning with the feeder that supplies the converting machine with the glass tubing and ending with a fully automated system for quality checking. Specifically, the correct shape of the container is monitored at every step by a camera system that allows for self-adjustment operations in the case of small dimensional deviations. From the machine, the container is transferred to another line where its

Figure 4 The Danner and Vello glass-tubing processes, drawing glass horizontally and vertically, respectively.

Figure 5 Forming process from glass tube to vial. The various steps include glass heating and processing with pre-finishing and finishing tools.

Figure 6 Schematic representation of a glass container production line. Different manufacturing and inspection systems are shown, including a tube feeder, a rotating manufacturing stage, optical inspection devices, and an oven.

dimensional parameters are again controlled by optical and mechanical means. Where appropriate, before being annealed it is then subjected to additional operations according to the customer requirements such as washing, sulfur treatment, etc. Finally, the container is brought to an automatic packing machine, which is confined in a protected clean area, where the final optical control for cosmetic defects is performed.

This factory quality control is the key to guarantee the compliance of the final product with the specification requirements established by both the pharmacopeia and the pharmaceutical industry. Maximum care thus is taken in the converter operations to avoid scratches on the container body. Likewise, special precautions are taken in the machine feeding phase, and all container transfer and packaging operations are performed by robots.

4 Physical Resistance

The theoretical strength of a material is directly connected to the strength of its structural chemical bonds (Chapter 3.11, [4]). In silicate glasses, strong covalent

bonds are present, such as Si—O bonds with energies of about 400 kJ/mol. These features translate into very high theoretical strengths, which could be greater than 10 000 MPa for glasses and glass ceramics. But commonly used glasses have mixed covalent (strong) and ionic (weak) bonds and, moreover, present dispersed structural microheterogeneities. As a result, the theoretical tensile strength of borosilicate glasses can vary from 6500 to 9000 MPa. These values can never be met in practice since the actual strength of glass articles is substantially affected by the presence of surface flaws (Chapter 3.11). Indeed, contact with metal tools or other glass items often causes damages on the surface of glass articles. These surface flaws usually appear as scratches or micro cracks, which act as stress concentrators during mechanical loading.

Eventually, the mechanical stresses generated by these defects may result in breakage of the finished container. Owing to wear and manufacturing processes, these flaws are common in all materials, but their effects are mitigated in ductile materials by plastic flow, which relieves the stress concentrations. Under typical operating temperatures and timescales, however, glasses are brittle materials that display negligible plastic flow. As a consequence, surface defects induced by wear, friction sliding,

Figure 7 As apparent in a probability plot for vertical breaking of cartridges, the considerable improvement in mechanical properties of cartridges produced in a *no-glass-to-glass* line (right) with respect to a standard production (left).

and impacts significantly decrease the mechanical resistance of glass containers [5], so their practical tensile strength is usually about only 20–200 MPa.

Interestingly, the failure of glass products also depends on the loading time and on the area subjected to the mechanical stress. Tensile stresses exerted over large periods of time may cause microscopic cracks to grow and eventually to reach critical sizes. This is why the strength of glass articles is higher for rapid than for slow mechanical loading. In addition, increasing the area subjected to mechanical stress increases the probability of triggering surface flaws, jeopardizing the resistance of the article. All these factors may differ widely from a process to another as illustrated by the considerable differences in vertical breaking probabilities between cartridges produced by two different processes (Figure 7): especially for the “weak” end of the distribution, considerable improvements are obviously provided by the *no-glass-to-glass* line products where the flaws coming from the mutual contact of containers are avoided.

5 Chemical Resistance

5.1 Corrosion Reactions

The chemical resistance of pharmaceutical glasses is the resistance to the attack by a liquid medium [6–9]. Although glass is almost inert with respect to the majority of neutral organic media, interaction with aqueous solution causes substantial alterations of the inner contact surface (Chapters 5.11 and 5.12). The resistance to such attacks by aqueous solution is known as the chemical durability or hydrolytic resistance (Chapter 5.1).

The chemical durability of soda-lime commercial glasses has been investigated for nearly a century [10, 11], so the interaction mechanism is well understood. In the field of pharmaceutical glass, borosilicates are recognized as the most durable because their interaction with semi-neutral aqueous solutions does not cause a significant pH shift. The reason is that alkalis are much more tightly bound to the silicate network when present as charge-compensating cations for B^{3+} in tetrahedral coordination (Chapter 7.6) than when being network modifiers as in soda-lime-silica glasses. In other words, borosilicate glasses are properly called *neutral* because the small amounts of alkalis and other ions released by the glass surface do not alter the neutrality of the contact solution.

When an aqueous solution enters in contact with the glass surface, the first stage is the hydration of the contact glass layer according to the reaction

At the same time an ion exchange reaction is initiated between alkali ions in the glass network and proton ions in the leaching solution

This reaction causes a slight rise of the pH of the extraction solution, which has a negligible effect on the extraction mechanism. The silica gel layer that forms on the surface differs in mechanical properties from the bulk glass. Repeated hydration and dehydration cycles

thus bring to the cracking of such layer and eventual generation of subvisible or visible particles. At this stage the quantity of extracted alkalis linearly correlates with the square root of time (t) but later on the process becomes linear with time (Chapter 5.11). The total extracted amount of alkalis (Q) can be schematically represented by the empirical expression $Q = a\sqrt{t} + bt$, where a and b depend on the glass composition and temperature [10].

For a slightly acidic medium, the following reaction takes place:

With solutions at pH lower than 4, the reaction proceeds up to the formation of an alkali-depleted layer that acts as a barrier toward further attack, whereas the pH remains substantially unchanged. For basic solutions (pH > 9), the OH^- ions break oxygen bridges ($\text{Si}-\text{O}-\text{Si}$ bonds), causing silica to dissolve according to the following dissolution mechanism:

With increasing OH^- concentration, the reaction shifts to the right, thus favoring the dissolution of silicic acid. In addition to pH, time, and temperature, other factors like the surface-to-volume ratio, glass composition, and the contact media determine the extent of chemical attack. For instance, buffers with a strong ionic strength (KCl and citric acid, for instance) or complexing agents such as EDTA, glutaric acid, and phosphate promote extensive interactions with the glass network and cause its total dissolution [12].

5.2 Testing of the Hydrolytic Resistance of Containers

The pharmacopeia distinguish between the resistance provided by the glass itself and that offered by the inner glass surface of the container in contact with water or, more generally, with aqueous preparations.

A *grain test*, carried out on a glass fraction of specified grain size, is suitable to monitor the resistance offered to water attack by the glass as material. In this respect, the distinction between type I and type III glasses becomes obvious when the extract solutions are titrated with a 0.02 M HCl solution after 30 minutes water exposures at 121 °C. The higher quality of borosilicate glasses (type I) manifests itself with a limit of 0.1 ml of HCl solution per gram of glass compared with a value of 0.85 ml for soda-lime glasses (type III). This test can be used also to reveal whether the glass surface has been treated or

Table 2 Comparison between glass grain test results for borosilicate glass tubes and molded soda-lime-silica glasses commercially available.

Supplier	Results (ml 0.02 M HCl/g glass)	Limit value (ml 0.02 M HCl/g glass)
Schott Fiolax	0.037	0.10
NEG BS	0.035	0.10

Corning	0.036	0.10
Soda-Lime Molded	0.44–0.54	0.85
Soda-Lime Amber	0.53–0.68	0.85

Table 3 Typical surface test results for type I vials produced by different glass-tubing converters using the same tubing raw material.

Vial capacity	Results (ml 0.01 M HCl/ 100 ml extract)	Limit value (ml 0.01 M HCl/ 100 ml extract)	Notes
3 ml	1.1	1.3	Converter A
3 ml	0.70	1.3	Converter B
10 ml	0.70	0.80	Converter C
10 ml	0.55	0.80	Converter B
20 ml	0.27	0.60	Converter B
2 ml	0.39	0.60	Converter C

not and, thus, to distinguish between type I and type II glass containers. In Table 2 typical *grain test* results from commercially available tubing and molded soda-lime glasses are reported.

A *surface test* is mandatorily requested to assess the alkali release from the inner surface of the containers. The latter, filled with water, are autoclaved for one hour at 121 °C, and the pooled extract is titrated with a 0.01 M HCl solution. The limit values are established as a function of container capacities and glass type, being 10 times higher for type III glass containers. Typical *surface test* results on vials of different capacity are displayed in Table 3 where the impact of different converters is also highlighted. In particular cases the individual alkali release can be measured by flame atomic absorption spectroscopy (Chapter 5.1).

5.3 Glass Extractables

There is an increasing attention paid to extractables, i.e. the substances released from the whole drug packaging system after a stress treatment (e.g. autoclaving treatment, long time and high-temperature exposure).

Table 4 Inductively coupled plasma mass spectrometry (ICP-MS) analyses of elements extracted from 10 ml glass type I vials after an autoclaving cycle made according to the *grain test*.

Element	Conc. (mg/l)	Element	Conc. (mg/l)
Cd	<0.01	Sn	<0.01
Pb	<0.01	Ni	<0.01
As	<0.01	Sb	<0.01
Hg	<0.01	V	<0.01
Cu	<0.01	Mn	<0.01
Fe	<0.01	Zn	<0.01
Se	<0.01	Co	<0.01
Ag	<0.01	Au	<0.01
Tl	<0.01	Li	<0.01
Ba	<0.01	Os	<0.01
Pd	<0.01	Pt	<0.01
Rh	<0.01	Ru	<0.01
Cr	<0.01	Mo	<0.01

Several regulations like ICH Q3D and USP <232> have been recently issued on this topic.

These regulations focus the attention on specific elements according to their potential final toxicity. Typical such elements are Cd, Pb, As, Hg, and hexavalent chromium.

Except arsenic, which is sometimes added to the glass batch as a refining agent, none of these elements is intentionally added (Chapter 1.2). They are present in the glass only as impurities in the starting raw materials, most of the times at ppm levels (mg/kg), and find themselves encapsulated in the glass network after melting. Their mobility is almost negligible under normal conditions of use, being extracted only under severe conditions (water at 121 °C for one to two hours, basic extraction at 80 °C for a 24–48 hours, etc.). Thanks to its inertness, glass thus is releasing an extremely limited amount of these elements even after water extraction is performed according to the *surface test* cycle. As illustrated by the data of Table 4, the values found are below the limits of detection of inductively coupled plasma mass spectrometry (ICP-MS), one of the most sensitive analytical techniques used for trace elements (Chapter 5.1).

6 Surface Interactions with Pharmaceutical Products

6.1 General Features

The primary packaging of glass is of paramount importance for parenteral drugs since it represents the first

interface in contact with the therapeutic agent. Different containers interact in specific manners with the drug products depending on their particular shape, the manufacturing process (e.g. forming from glass tubes, internal siliconization), and the assembled components (e.g. plungers, stoppers, needles, etc.). Containers are thus carefully monitored during the entire product shelf life to ensure that the therapeutic characteristics of the drug are not compromised.

Vials have been commonly employed for storage of drugs over long time periods. Under particular conditions, however, the enclosed drug formulation can interact with their inner surfaces. Eventually, this interaction could also lead to glass *delamination*, i.e. the detachment of small lamellae from the glass surface. This potential problem must be specially taken into account for injection systems such as syringes and cartridges, which, as already stated, are becoming more and more common as parenteral packaging solutions thanks to their usability and dosing accuracy. Compared with traditional vials and ampoules, syringes and cartridges in effect differ by the fact that they are exposed to more components with which they could react. As will be described below, the drug compatibility with tungsten, silicone oil, and leachables from stoppers and tip caps, for instance, should be assured throughout the product shelf life.

6.2 Delamination

The appearance of visible glass particles, generally known as flakes (lamellae), in injectable preparations has caused a number of drug product recalls in 2010–2011 [13]. This delamination phenomenon has been well documented in the glass literature ever since the early 1940s when the occurrence of flakes in soda-lime glass bottles exposed to uncontrolled humidity and temperature conditions was described [11, 14].

The mechanism of glass delamination in pharmaceutical glass vials is described in Figure 8. The first stage is the formation of an altered layer caused by either extreme thermal treatments during the forming process or contact with very aggressive substances [15]. Strains are then established between the altered layer and the bulk glass having different thermal expansion coefficient. Therefore when vials are filled with the liquid preparation, this mechanically weakly linked layer is subject to a strong hydration and swelling that cause the detachment of flakes (lamellae) [16].

Many factors determine the delamination propensity of pharmaceutical glasses. A major one is the presence or absence of the surface treatments described in Section 7 (ammonium sulfur treatment, siliconization) or special coatings, which are purposely intended to produce a deep modification of the outmost surface layers.

Figure 8 Mechanism of glass delamination in pharmaceutical glass vials. Inset: altered layer on the glass surface, which may detach as a flake.

The type of glass used, (e.g. CTE 33, CTE 51) or other factors such as the B_2O_3 content, in combination with the drug may play an important role on the final container delamination propensity. The nature and the pH of filling media, the presence of organic acids, and the formulation of the buffer system can trigger an extensive alteration of the glass surface together with the washing and depyrogenation process, the sterilization operations, and the storage conditions.

Reducing the risk of delamination is therefore not a simple exercise, as one has to consider and keep under control all the production stages, starting from the choice of the most appropriate glass type as a function of the chemistry between glass and the pharmaceutical solution, the optimization of the glass container forming process, the subsequent filling operations, and the shelf life of the product. These checks should be made in accordance with the European Pharmacopoeia, which, for instance, states that “Accelerated degradation testing can be used as a predictive tool to select the most appropriate container for the intended preparation, but the full compatibility of the active substance with the glass leachate can only be assessed by a stability test under normal conditions of use.”

6.3 Tungsten

Recent studies have shown that soluble tungsten polyanions may cause the precipitation and/or the aggregation of biomolecules such as monoclonal antibodies to form visible particles. It has also been reported that exposure of proteins to increasing concentrations of tungsten polyanions in acidic pH strongly favors aggregation and may induce reduced activity and increased immunogenicity.

Although borosilicate glass containers do not contain tungsten, a tungsten-containing pin is kept in contact with the glass tip during the cone formation of glass syringes to form the bore where the needle will be accommodated in a later stage. The use of pins at elevated temperatures favors the formation of tungsten oxides (WO_3 and WO_4), which evaporate and interact with the outmost glass surface of the funnel. They then form soluble sodium tungstate polyanions, which are easily extractable. When present, sodium tungstate can be observed as white spots in scanning electron micrographs of the inner surface of the funnel (Figure 9). Hence, the maximum permissible concentration of tungsten that is deemed not to cause any adverse effect to

Figure 9 Tungsten residues of the inner surface of a syringe cone as seen as bright zones in a scanning electron micrograph compositional image (92× magnification). Courtesy Giovanni Stevanato Laboratory (Ca' Foscari University of Venice, Italy).

biopharmaceuticals, around 500 mg/l, can be respected only through a very controlled and precise forming process of the syringe cone.

6.4 Particle Release

The European, US, and Japanese pharmacopeias have set limits and provide techniques for detecting and quantifying visible and subvisible particulate in parenteral solutions that might compromise the safety of the patient. Glass containers must actually be “practically free” from visible particles [17]. These regulations provide limits for *extrinsic* particles, such as hair and dust, in terms of a maximum allowed number depending on particle size. In particular, limits set for the number of subvisible particles are 6000 for particles greater than 10 μm and 600 for particles greater than 25 μm . The regulations set also limits for *intrinsic* and *inherent* particulates. Intrinsic particles originate from the production process. They are usually composed of silicone oil, stainless steel, or glass. Inherent particles, on the other hand, are product related – an example is given by protein particles in biotechnological formulations. Current processes have drastically reduced the size and occurrence of particles, and the latest technological advances have significantly improved their detection and quantification. The three types of particulate are carefully monitored in glass primary packaging.

In particular, silicone oil subvisible particles may migrate from a siliconized container (typically prefilled syringes) to the drug solution. Also, the movement of the stopper during the injection may ease the migration of silicone oil into the drug. This concern can become serious when the number of dispersed particles exceeds the limits set by the pharmacopeia. The presence of silicone oil may also accelerate aggregation in proteins and, when injected, aggregates elicit immunogenic responses [18].

7 Internal/External Treatments for Chemical/Mechanical Resistance

A large array of solutions is available to address the aforementioned corrosion and interaction issues. These solutions come in the form of internal or external treatments, which can be applied to glass containers to improve their resistance. Some of them have become standard in the manufacturing practice, whereas others are still an area of active research. The three most common treatments are ammonium sulfate treatment, siliconization, and glass strengthening.

7.1 Ammonium Sulfate

The ammonium sulfate treatment was originally designed to improve the chemical durability of the inner surface of type III glass containers. The process is carried out on molded soda-lime containers before entrance into the annealing lehr. The ammonium sulfate solution is sprayed in-line on the highly reactive surface of the virgin vial. The reaction occurs according to the following scheme:

This treatment extracts alkaline and earth alkaline elements from the surface and generates a bloom made of alkali sulfate salts that confer an opalescent aspect to the containers. This layer is easily removed in a subsequent washing step that leaves behind a silica-enriched surface for a depth that depends on the penetration of the treatment, generally down to 0.5 μm . As a result, the containers become classified as type II because they have an excellent chemical durability, comparable with that of type I, but restricted to a thickness of a few hundred nanometers below the surface. Alternative treatments with 1-2-difluoroethane or gaseous sulfuric acid are occasionally used for molded vials at the same purpose.

The same treatment can be applied to type I glass containers before the annealing lehr and specifically on containers filled with drugs or solvents particularly sensitive to pH shifts. The advantages of the sulfur treatment are a reduction of alkali release, an easier compliance with pharmacopeia and an easy integrability of the process in the production lines. As for its disadvantages, they are of course an increased cost due to the additional processing step but especially the creation of surface inhomogeneities, which increase dramatically the risk of glass delamination when the thickness of the modified surface layer increases.

7.2 Siliconization

Prefilled syringes and cartridges operate through a plunger that moves along the inner surface of the glass barrel. To ensure the smooth movement of the plunger, silicone oil is commonly employed as a lubricant. In Section 6.3, however, there is evidence that proteins may form aggregates by interactions with it. Nonetheless, a lubricant is necessary to guarantee suitable values of break-loose and glide forces and enables a correct fluid

flow during injections. Internal treatments have therefore been developed to deposit a layer of silicone oil on the glass surface so that detachment of silicone particles can be reduced and the mechanical gliding properties can be assured [19]. The layer of silicone oil is characterized by two main parameters: the quantity of silicone oil applied to the container barrel and its distribution. An excess of silicone oil may slough off from the barrel and generate particles, so care has to be taken to deposit only the proper amount. Moreover, the silicone oil should be applied homogeneously throughout the container internal surface, so the degree of lubrication is constant along the plunger path.

Two main methods are currently employed to perform siliconization of pharmaceutical glass containers. In *spray-on* siliconization, the silicone oil is sprayed from a moving nozzle along the container barrel. The movement of the nozzle and the quantity of silicone that is sprayed have to be carefully controlled to achieve uniform distribution. In *baked-on* siliconization, a silicone oil emulsion is first sprayed on the container inner surface and then baked at high temperature. In the literature, baking temperatures from 100 to 320 °C have been reported, depending on the desired characteristics of the silicone layer that forms and on the silicone oil composition. A thin layer of silicone oil directly on the glass becomes partially bonded to the surface during the baking stage. At the end of the process, the combination of bonds to the surface and polymerization contributes to the adhesion of silicone oil to the glass barrel. Baked-on siliconization leads to decreased migration of silicone oil into the drug product without seriously compromising the functionality of the lubrication. However, a careful selection of the operating temperatures and times has to be performed as the silicone bulk properties could change through thermal decomposition during the baking phase. Recently, novel coating methods utilizing cross-linked silicone have been developed to reduce further silicone sloughing off from the container barrel. Silicone oil-free systems such as low-friction plungers and stoppers that could enable suitable gliding performances in silicone-free glass containers are now under investigation.

7.3 Glass Strengthening

Because most of the strength-limiting defects in glass articles are created by mechanical contact or localized thermal shock, attention has to be focused on the manufacturing and transportation processes. For pharmaceutical applications, the use of an appropriate glass-tubing converting process can limit the presence of surface

flaws in the glass, allowing the production of glass containers with increased mechanical strength.

If a particular mechanical resistance of the glass container is requested, a *chemical* strengthening processes (ion exchange) can be applied. Since the process is described in Chapter 5.12, it will suffice here to state that the glass container is submerged into a molten potassium nitrate salt. An ion exchange process takes place, in which sodium ions of the glass are replaced by potassium ions from the bath. As the potassium ions are bigger than the sodium ones, their presence in the surface creates a state of compression. The depth profile of the potassium layer is tuned to the bath temperature and time. Suitable depths of the potassium layer can produce compressive surface states that limit the effects of surface defects, considerably increasing the mechanical performances.

8 Perspectives

Even though glass has been used for a long time to store pharmaceuticals, advances in glass composition, container performance, and glass treatments are still important areas of research. As a matter of fact, the synergy between glass manufactures and pharmaceutical companies is getting stronger every day. An example of this is given by novel therapies for which there is a need for containers that are able to protect and store more complex and aggressive formulations throughout the product shelf life. An increased level of flexibility is thus requested by the market, with the constraint of satisfying all the requirements that guarantee the quality of the product. One can achieve this objective by improving manufacturing process, applying new treatments, and using new glasses compositions. For example, coatings could be developed to improve the adhesion of silicone oil on the inner surface of glass containers.

There is a general worldwide action for the reduction of the costs associated to healthcare. As a consequence, self-administration of drugs is becoming more and more common. A transition from infusion to subcutaneous injections is progressively taking place for diseases such as diabetes and cancer treatments. This trend is driving the development of new container formats, whose shapes and volumes are determined by the new therapies and drugs. The very concept of glass for pharmaceutical packaging is evolving: from a mere container to store the product, glass is becoming a fundamental part of medical delivery devices. In these systems, the packaging and the drug are fully integrated to provide the maximum efficacy of the therapy. To be realized, this transition must be performed through a rational approach. The

interactions between the glass and the therapeutic formulation have to be further deeply investigated on a scientific basis to characterize the occurring phenomena and understand their implications on drug stability. Solid theoretical and statistical grounds should guide the optimization of the manufacturing process, so the quality of the final product is pursued from the design stage to the final use by the patient.

Oxynitride Glasses

Stuart Hampshire and Michael J. Pomeroy

The Bernal Institute, University of Limerick, Limerick, Ireland

1 Introduction

In oxynitride glasses, oxygen atoms are partially replaced by nitrogens in the silicate or aluminosilicate network [1–4]. Oxynitride glasses have been synthesized with different modifying cations such as Li [5], the alkaline earths (Mg, Ca, Ba, Sr) [1, 6, 7] or Y [1–4, 8], and the rare-earth lanthanides (Ln) [3, 4, 9] as well as mixed modifiers [10].

Following some early work on solubility of nitrogen in soda-lime-silica glasses [11], it was discovered that silicon-nitride-based ceramics contained oxynitride glass phases in grain boundaries when oxide additives were used for liquid-phase sintering of the product [12]. The main oxide additives used were yttria and alumina. They react with the silicon nitride and silica on its particle surfaces to form a Y–Si–Al–O–N liquid phase at high temperatures, which subsequently cools to form intergranular glass films. Interest was then further stimulated, particularly in Y-modified oxynitride glasses, because the chemistry and volume fraction of the intergranular glass phases determined the properties of the material, particularly their ambient and high-temperature mechanical behavior.

Further studies of the formation, structure, and properties of bulk oxynitride glasses showed them to have higher elastic modulus, hardness, glass-transition temperature, and viscosity than their oxide glass counterparts as a result of extra cross-linking of the glass network when nitrogen substitutes for oxygen [1–4, 8–10]. Thus, oxynitride glasses became one additional type to the range of specialty or “new” glasses with novel functions which

have potential for use in modern industrial sectors such as optoelectronics, microelectronics, communications technologies, biomedical devices, and niche areas of the automotive and architectural sectors.

In this chapter, we will first describe why so much nitrogen can dissolve and how the complex compositions of these materials are conveniently pictured in terms of Jänecke’s prism. The peculiar structural features and stronger atomic bonding of oxynitride glasses will then be discussed before the composition dependence of their physical properties is presented. Finally, glass–ceramics, phosphate glasses, and ways to make preparation of these materials easier are presented.

2 Solubility of Nitrogen in Glasses

The physical solubility of nitrogen in soda-lime-silica glasses is extremely low if the gas is bubbled through the melt (Chapter 5.5, [11]). If ammonia gas is bubbled instead for five hours at a temperature of 1400 °C, however, the chemical solubility of nitrogen in the glass reaches 0.33 wt %. From this value some 10⁵ times higher than that for physical solubility, it was proposed that nitrogen substitutes for oxygen in the SiO₄ tetrahedra within the silicate network when conditions are reducing [11]. This substitution leads to a higher than average coordination of nonmetal atoms as in:

Reviewers: T. Rouxel, LARMAUR, Université de Rennes, Rennes cedex, France

P. Šajgalík, Institute of Inorganic Chemistry, Slovak Academy of Sciences, Bratislava, Slovakia

This results in increased cross-linking and, hence, a more rigid glass network.

A further study [13] found that, by heating in ammonia, 3 wt % N could be incorporated into the structure of porous borosilicate glasses, used as high-energy lamp envelopes, which resulted in increases in annealing temperature, indentation hardness, and electrical resistivity, and a significant decrease in thermal expansion coefficient. Devitrification of these glasses can be induced electrolytically as a result of buildup of alkali ions in the cathode region caused by their migration under the influence of the electric field. The presence of nitrogen had the interesting feature of inhibiting the transformation, an effect attributed to the increased viscosity caused by the existence of (=NH) and (=N—) groups in the structure.

An investigation of the solubility of nitrogen in CaO–SiO₂–Al₂O₃ metallurgical slags [14] found that, from 0.25 to 2.5 wt %, N is dissolved into the melt after 24 hours in a 0.1 MPa nitrogen atmosphere. By contrast, when Si₃N₄ is added to the melt, under the same conditions, 4 wt % nitrogen is incorporated much more rapidly. Hence, it was concluded that most silicate melts are not significantly reducing enough to dissolve gaseous N₂ or NH₃ so that it is necessary to dissolve instead nitrogen from nitrides such as Si₃N₄.

Since the early days of the development of silicon-nitride-based ceramics [12], the impetus for studying bulk oxynitride glasses has come from a growing desire to understand the nature of the intergranular glass phases. Typically, the preparation of these glasses [1–4] involves wet-ball milling of appropriate powders – silica, alumina, the modifying oxide plus silicon nitride or aluminum nitride – in isopropyl alcohol with sialon milling media, followed by evaporation of the alcohol. Batches of up to 50–60 g are melted in boron-nitride-lined graphite crucibles under a 0.1 MPa nitrogen pressure at 1650–1750 °C for 1 h, after which the melt is poured into a preheated (~850 °C) graphite mold. The glass is annealed close to its glass-transition temperature (T_g) for one hour to remove stresses and then slowly cooled. In accordance with the tight nature of the bonds formed by nitrogen in the material, weight losses during melting are usually less than 1%.

3 Glass Formation in M–Si–Al–O–N Systems and Its Representation

Convenient methods of representing both Si–Al–O–N and M–Si–Al–O–N systems involve the concept of reciprocal salt pairs. The four-component Si–Al–O–N system is a square plane which has, as components, the

Figure 1 Jänecke's triangular prism for the Y–Si–Al–O–N system showing the complete glass-forming region for melts quenched from 1700 °C. Source: After Ref. [1].

oxides and nitrides of silicon and aluminum. The introduction of a further cation gives a five-component system represented by the so-called Jänecke's triangular prism shown in Figure 1 for the Y–Si–Al–O–N system, in which the boundaries of the complete glass-forming region are outlined [1].

As is usual in these systems, the concentrations of all components will be expressed in equivalents instead of atoms or gram-atoms. One equivalent of any element always reacts with one equivalent of any other element or species. If the top right-hand corner of the basal square represents one mole of Si₃N₄, then moving from right to left, 3 Si⁴⁺ are gradually replaced by 4 Al³⁺ and, from top to bottom, 4 N^{3–} are replaced by 6 O^{2–}, so that the corners of the square are Si₃N₄, Si₃O₆, Al₄O₆, and Al₄N₄. Any point on the square represents a combination of 12 positive and 12 negative valence units.

When moving into the prism, the third modifying “cation” (M = Y, Mg, RE, etc.) also needs to be taken into account. Any point in the prism represents a combination of 12 positive and 12 negative valence units. For a system containing three types of cations, A, B, and C with valences of v_A , v_B , and v_C , respectively, then:

Equivalent concentration of A

$$= (v_A [A]) / (v_A [A] + v_B [B] + v_C [C]), \quad (1)$$

Equivalent concentration of B

$$= (v_B [B]) / (v_A [A] + v_B [B] + v_C [C]), \quad (2)$$

Equivalent concentration of C

$$= (v_C [C]) / (v_A [A] + v_B [B] + v_C [C]), \quad (3)$$

where [A], [B], and [C] are the atomic concentrations of A, B, and C, respectively, in this case, Si^{IV}, Al^{III}, and Y^{III}.

If the system also contains two types of anions, D and E with valences ν_D and ν_E , respectively, then:

$$\text{Equivalent concentration of D} = (\nu_D [D]) / (\nu_D [D] + \nu_E), \quad (4)$$

$$\text{Equivalent concentration of E} = (\nu_E) / (\nu_D [D] + \nu_E), \quad (5)$$

where [D] and [E] are the atomic concentrations of D and E, i.e. O^{II} , N^{III} , respectively. The concentrations can then be expressed as equivalent percentages (eq. %). Any vertical plane within the prism has a constant nitrogen: oxygen ratio.

The limits of the metal aluminosilicate glass regions are plotted on the oxide face of the prism. The glass-forming region is seen to expand initially as nitrogen is introduced and then diminishes above approximately 10 eq. % N until the solubility limit of nitrogen is exceeded. Depending on the particular network-modifying cation, up to 25–30 eq. % N can be introduced into the glass.

In M–Si–O–N systems, much smaller glass-forming regions are observed (Figure 1). This feature confirms the ability of Al_2O_3 to extend the range of glass formation in both silicate and oxynitride systems. The miscibility gap in various silicate binary systems (Chapter 5.2) expands to a small extent into the equivalent M–Si–O–N system with consequent phase separation in some low-alumina glasses.

4 Structure of Oxynitride Glasses

4.1 Si–N Bonding

Early analyses of oxynitride glasses by IR spectroscopy confirmed the formation of Si–N bonds in the atomic network which, by substitution for oxygen, produces a more tightly and highly linked structure. Oxygen can coordinate with up to two Si atoms in the glass network bridging between two SiO_4 tetrahedra (Figure 2a). Nitrogen, in contrast, may be coordinated with up to three Si atoms [15] or alternatively bond with two SiO_4 units and a network-modifying cation such as Mg^{2+} or Y^{3+} (Figure 2b and c, respectively).

With ^{29}Si MAS-NMR spectroscopy it has been shown that the oxynitride network contains SiO_4 , SiO_3N (and possibly SiO_2N_2) tetrahedral structural groups [4, 16]. The $[SiO_3N]^{5-}$ group requires the presence of an extra positive charge locally to balance the extra negative charge from the N^{3-} anion. The situation is, therefore, very similar to that of an $[AlO_4]^{5-}$ tetrahedron within the glass network, which also requires an extra positive charge to make it isoelectronic with the $[SiO_4]^{4-}$ tetrahedron. For this reason, oxynitride glasses containing SiO_3N groups can

Figure 2 Bridging of SiO_4 tetrahedra. (a) Via a bridging oxygen connecting two SiO_4 units in silicate glasses; (b) via a bridging nitrogen connecting three SiO_4 units in oxynitride glasses; (c) or via a bridging nitrogen connecting two SiO_4 units and a network-modifying cation such as Y^{3+} . Source: After Ref. [4].

accommodate more modifiers in “charge compensating” sites than the equivalent oxide glasses without creating non-bridging oxygen (NBO) species.

Whereas strength is greater for the Si–O bond ($U_{Si-O} = 800$ kJ/mol) than for the Si–N bond ($U_{Si-N} = 437$ kJ/mol), calculations show that the latter is more resistant to bending [4]. Along with the increased coordination with Si, the effect is to increase the rigidity of the network because bonding is much more covalent for Si–N than for Si–O so that bending is more difficult for Si–N–Si than for Si–O–Si linkages.

4.2 Aluminum Incorporation

In oxynitride aluminosilicate-type glasses, Al (as well as Si) can be in fourfold coordination with oxygen and so act as a network former [2, 4] although the Al–O network

bond is somewhat weaker (and less covalent) than the Si–O bond. The difference in charge between Al^{3+} and Si^{4+} also requires the presence of an additional cation locally for local charge balance. Thus, Y^{3+} and Mg^{2+} would serve to balance the charges of three and two AlO_4 tetrahedra, respectively. As a modifier, yttrium has an affinity to bond with oxygen, coordinating with five or so oxygens based on results for yttrium aluminosilicate glasses [4]. For oxide glasses with a considerable ionic bond character, some general insights into the relative strengths of various M–O bonds (M = cation) can be gained from Coulombic interactions between a cation and an anion through cation field strength ($\text{CFS} = v/r^2$, where v is valency and r ionic radius). This picture, however, becomes more complicated with the introduction of strong covalent bonds (Si–N or M–N) in oxynitride glasses. Although the Y–O bond is weaker than the oxygen bond with either Si or Al, its coordination with multiple oxygens and the associated high CFS indicate that Y can improve the strength of the glass network.

4.3 Si–N vs. Al–N Bonding

For glasses with nitrogen contents up to about 20 eq. % N, MAS-NMR, FTIR, and Raman-spectroscopy studies have indicated that Si–N is preferred to Al–N bonding [9, 16]. Thus, it is possible to estimate the average number of nitrogens preferentially bonded to each silicon, i.e. x in each $\text{SiO}_{(4-x)}\text{N}_x$ tetrahedron within the glass network. For most glasses this number of nitrogens per tetrahedron varies as a function of nitrogen content without exceeding 1 until a nitrogen content of 15 eq. % is reached (Figure 3).

For a glass with a composition of 37Y : 42Si : 21Al ratio, i.e. with a higher Al : Si ratio, more than one nitrogen is bonded to a given silicon if the nitrogen content exceeds about 10 eq. %. For another glass with a composition of 21Y : 48Si : 31Al containing about 10 eq. % N, MAS-NMR data [6] indicate that one nitrogen is bonded to each silicon, which is in reasonably good agreement with the calculated value of 0.8. Accordingly, a simple calculation of the average number of nitrogens per silicon gives a reasonable estimate of the anion environment of silicons.

Virtually all Al-containing oxynitride glasses studied in detail have sufficient modifier cations to charge balance aluminum in fourfold coordination. However, the Al coordination with oxygen changes from four to five and sixfold as the Al : Si ratio increases in Y–SiAlON glasses with fixed Y and N contents [2, 17]. Whereas more Al–O–Si linkages are formed by displacement of Si–O–Si linkages, little change in the number of NBOs or in the degree of network cross-linking occurs. However, more five and sixfold coordinated Al atoms are observed when the Al : Y ratio decreases in glasses with fixed Si and N contents, and the number of NBOs actually increases

Figure 3 Average number of nitrogen atoms bonded to each silicon as a function of nitrogen content for glasses with different cation ratios (compositions expressed in eq. %). Ln represents a lanthanide (La, Nd, Sm, Gd, Yb, Er, Lu) or yttrium. Source: After Ref. [9].

because of a decrease in Si–O–Al linkages [4, 17]. The chain-like or sheet-like structures formed from $\text{Si}(\text{O},\text{N})_4$ (or AlO_4) tetrahedra are also increasingly cross-linked by Al linkages to oxygen at the tetrahedron corners as the Al content increases.

Raman spectroscopy [4] provides insights into the number of bridging oxygens (BOs) (or anions) associated with a Si-based tetrahedron, which are denoted by Q^n values, from which the relative percentages of BO and NBOs present in the glass may be obtained (Chapter 2.3). Results on the effects of nitrogen content in an Er–Si–Al–O–N glass show that a portion of each tetrahedron with only three BOs is converted to a tetrahedron with four bridges (i.e. O and N) with increasing nitrogen content. These results imply that nitrogen is incorporated into what was a non-bridging site (similar to that shown in Figure 2c). Other Raman studies [4] for oxide and oxynitride glasses with cation compositions of 55Si : 20Ln : 25Al and 45Si : 30Ln : 25Al (Ln = rare-earth lanthanide) indicate there is a shift to a greater number of Si tetrahedron bridges (i.e. an increased population of higher Q^n values) as the ratio of Si to Ln increases. This trend indicates that Si–O–Si bridges are promoted at the expense of Si–NBO–Ln linkages when Si replaces Ln, resulting in an overall increase in network connectivity. In both these oxide and oxynitride series, the number of Si tetrahedron bridges tends to increase as the size of the Ln cation decreases (as CFS of Ln increases), thus promoting greater network connectivity.

4.4 Vibrational Density of States

The substitution of N for O implies changes in the vibrational density of states $g(\omega)$ and, therefore, in the low-temperature isobaric heat capacity, C_p , which is a sensitive function of short- and medium-range order at low temperatures (<200 K). The effect of the substitution of nitrogen for oxygen on the heat capacity and vibrational entropy of three Y–Si–Al–O–N glasses with increasing N contents was investigated from 10 to 300 K [18]. The partial molar heat capacity and entropy of Si_3N_4 calculated from these and previous measurements indicate stronger average bonding than for SiO_2 units. The values derived for Y_2O_3 are consistent with both the network-modifying role of Y^{3+} and its role as a charge-compensating ion for $[\text{AlO}_4]^{5-}$ tetrahedra. These effects, along with previous elastic studies, represent the calorimetric measure of the increased rigidity and network cross-linking induced by the substitution of nitrogen for oxygen.

Inversion of the low-temperature C_p data [18] allowed the low-frequency part of the density of states to be determined. Of particular interest is the so-called boson peak, which represents either excess modes below 100 cm^{-1} compared with the $g(\omega) \propto \omega^2$ law or excess heat capacity below $\sim 50\text{ K}$ with respect to the T^3 limiting law of the Debye model. Part of the low-frequency excitations originates in the libration of a limited number of rigid TO_4 tetrahedra ($\text{T} = \text{Si}, \text{Al}$) around corner-sharing oxygens. It was observed that substitution of N for O, which enhances network cross-linking, causes a decrease in intensity of the boson peak which suggests a reduction in the librational motions of the TO_4 tetrahedra, consistent with an increased rigidity of the glass network.

In summary, the glass network in oxynitride glasses comprises $\text{SiO}_{(4-x)}\text{N}_x$ tetrahedra, with average x values controlled by N:Si ratios, which are bridged either by bi-coordinate O–T or tri-coordinate N–T linkages, and

also by AlO_4 tetrahedra which are mainly bridged by bi-coordinate O–T linkages. It is now appropriate to look at the effects of nitrogen substitution for oxygen on glass properties to determine how they are affected by replacement of bi-coordinate O–T by tri-coordinate N–T linkages and whether the effects depend or not on the nature of the modifier if the overall cation composition is kept constant.

5 Effects of Composition on Properties

5.1 General Features

As with all types of glasses, the properties of oxynitrides crucially depend on chemistry and, especially in this case, on nitrogen concentration. Early work on the correlations between nitrogen incorporation into oxynitride glasses and changes in their mechanical, elastic, and thermal properties suggested that the observed enhancement of these properties was due to increases in nitrogen content [8]. However, no account was taken of changes in Si : Al ratio or the modifying cation concentration and so changes in properties could not be attributed solely to nitrogen incorporation.

The first systematic studies on the effect of substituting oxygen by nitrogen in oxynitride glasses with constant cation compositions showed that for all Mg-, Ca-, Y-, and Nd–Si–Al–O–N glasses, increases in nitrogen did indeed result in increases in a range of mechanical, elastic, and thermal properties [1]. Further studies have investigated the effects of changes in cation ratios, keeping O : N ratio constant [2–4].

When cation ratios (M : Si : Al) are kept constant, linear correlations are typically observed between nitrogen content and various mechanical, elastic, and thermal properties [1] as summarized in Table 1 for

Table 1 Properties of oxynitride glasses.

Glass composition (eq. %)	28Y : 56Si : 16Al 0 N	28Y : 56Si : 16Al 17 N	28Er : 56Si : 16Al 17 N	35Y : 45Si : 20Al 17 N

28Y : 56Si : 16Al glasses either with 0 and 17 eq. % N or when 28 eq. % Y is replaced by 28 eq. % Er, as well as for 35Y : 45Si : 20Al : 83O : 17 N glasses.

5.2 Mechanical and Elastic Properties

When cation ratios (M : Si : Al) are kept constant, linear correlations are observed between nitrogen content and Young's modulus or hardness [1] (Figure 4). For a 28Y : 56Si : 16Al glass, Young's modulus increases by some 35% from 112 GPa at 0 eq. % N to 149 GPa at 17 eq. % N (Table 1). A detailed analysis of 28(Mg + Y) : 56Si : 16Al glasses showed that the slopes of plots of Young's modulus vs. nitrogen content are the same for each of three different modifier compositions used: 28 Mg : 0Y; 14 Mg : 14Y; 0 Mg : 28Y [10]. For the Mg-modified 28 Mg : 56Si : 16Al glass, Young's modulus increases by 17% as 15 eq. % N is substituted for oxygen.

For other elastic modulus and microhardness data, most reports show also good linear relationships between property values and nitrogen content with correlation coefficients generally of the order of 0.99. For elastic modulus, gradients of the plots are in the range 0.8–1.8 GPa (eq. % N)⁻¹. Thus, the substitution of 20 eq. % N for oxygen in these glasses would be expected to increase Young's modulus by values between 16 and 36 GPa. For microhardness, the gradients lie in the range 0.07–0.13 GPa (eq. % N)⁻¹, most gradients being close to 0.1 GPa (eq. % N)⁻¹ so that substitution of 20 eq. % N for oxygen would increase the microhardness of the glass by ~2 GPa.

When the Si and N contents are fixed, the values of E increase when Al is replaced by Y, such that increases

in the Y : Al ratio have the same effect on E as increasing N content.

For rare-earth lanthanide (Ln)–Si–Al oxynitride glasses, Young's modulus increases with the cationic field strength (decrease in ionic radius), which is attributed to the increasing compactness of the glass network.

Oxynitride glasses provide a good illustration of the impact of the degree of cross-linking of the glass network on the elastic moduli. These glasses are clearly stiffer than their parent oxide glasses (with the same cation ratios). However, the values for the bonding energies do not fit with these trends: $U_{\text{O-Si-N}} (437 \text{ kJ/mol}) < U_{\text{O-Si-O}} (800 \text{ kJ/mol})$. The reason for the excellent stiffness of oxynitride glasses appears to have more to do with the 3-D bonding architecture, including the property of compactness or atomic packing density, rather than the bond strength per se.

5.3 Thermal Properties – Glass Transition Temperature, Softening Temperature, Viscosity, Thermal Expansion Coefficient

The effects of nitrogen content on glass-transition temperature (T_g) at constant cation ratios are summarized in Figure 5. As with mechanical properties, one observes excellent linear correlations between nitrogen substitution levels and glass-transition temperature. For a 28Y : 56Si : 16Al glass (Table 1), T_g , for instance, increases from 940 to 985 °C between 0 and 17 eq. % N, i.e. with a slope of ~2.7 °C (eq. % N)⁻¹. These gradients are actually in the range 2.6–4.1 °C (eq. % N)⁻¹ with most values close to 3.5 °C (eq. % N)⁻¹. Thus, for a 20 eq. % N substitution level, T_g is expected to increase by ~70 °C. Littleton and dilatometric softening temperatures also increase linearly with nitrogen content, the slopes for the latter being similar to those for T_g with values in the range 2.3–3.8 °C (eq. % N)⁻¹.

For lanthanide (Ln)–Si–Al oxynitride glasses, where the nitrogen to oxygen ratio is kept constant, the glass transition and softening temperatures tend to increase as the ionic radius of the rare-earth cation decreases, that is as cationic field strength increases [4, 9].

Oxynitride glass viscosity increases with increasing nitrogen substitution and, like glass-transition temperature and softening temperatures, varies linearly with nitrogen content as shown in Figure 6. As shown in Table 1, for a glass with composition (in eq. %) of 28Y : 56Si : 16Al, substitution of 17 eq. % N for oxygen results in an increase in viscosity of ~2 orders of magnitude.

However, there is quite a wide variation in viscosity with nitrogen content that depends on cation type and ratios. For an increase in nitrogen content from 0 to 20 eq. %, viscosity increases can vary between 2.0 and 3.6

Figure 4 Linear increases of Young's modulus of oxynitride glasses with increasing nitrogen content.

Figure 5 Glass-transition temperature (T_g) of oxynitride glasses increases linearly with increasing nitrogen content.

Figure 6 Effect of nitrogen content on viscosity (log scale) for oxynitride glasses with various cation compositions (in eq. %) at temperatures of 875, 925, and 930 °C. Source: After Ref. [9].

orders of magnitude. These effects are a result of the increase in the rigidity and covalence of the bonding of the network with the addition of nitrogen, which would serve to inhibit relaxation of the network as the temperature increases. On the other hand, changes in the Si, Al, and Y contents have much smaller and sometimes opposing effects on the temperature-dependent viscosity profiles. At high Al : Y ratios, when four co-ordinated Al dominates, there is an enhancement of the cross-linking of the glass network, so reducing the number of non-bridging anions. At lower Al : Y ratios, there is a decrease in network compactness due to an increase in five- or six-co-ordinated Al atoms.

In rare-earth Ln–SiAlON glasses, the temperature-dependent viscosity shifts to higher temperatures as the

Figure 7 Schematic plot showing the combined effects of cation field strength and nitrogen content on the viscosity of Ln–Si–Al–O–N glasses at a fixed temperature.

lanthanide ion size decreases [9]. It is thought that these ions affect the molar volume in such a way that the smaller ions exert stronger bonding (i.e. higher CFS of the Ln ion) on the (Si, Al)(O, N)₄ tetrahedra and form a more compact network. In summary, glasses containing more N, less Al, and smaller Ln cations will have higher viscosities. Overall, a change of five to six orders of magnitude in viscosity can be achieved by careful modification of glass compositions as shown schematically in Figure 7. The activation energies for viscous flow increase as CFS increases so that, at any temperature, glasses with smaller cations have higher viscosities and the activation energies for viscous flow are higher, reaching values of >1300 kJ/mol for Lu–SiAlON glasses.

Although some data show negligible changes, many observers have reported decreases in coefficients of thermal expansion (CTE) with increasing nitrogen content at temperatures from just below the softening point down to ambient [4]. As shown in Table 1, for a glass with composition (in eq. %) of 28Y : 56Si : 16Al, substitution of 17 eq. % N for oxygen results in a decrease in CTE from 6.6 to $5.7 \times 10^{-6} \text{ K}^{-1}$.

When the Si and N contents are fixed, T_g values, as well as CTE, increase when Al is replaced by Y.

5.4 Fracture, Strength, Slow Crack Growth

Early results on the room-temperature flexural strengths of Li–K–Si–Al- and Y–Si–Al-oxynitride glasses indicated that there is no real effect of nitrogen content [4], but the surface conditions of the specimens were not given. Later work also reported [4] that the flexural strengths of oxide and oxynitride (17 eq. % N) glasses with

the cation composition 45Si : 20Al : 35Y in as-polished conditions are very similar. After annealing 20 °C below and above T_g , the strength of the oxynitride glass doubled and increased threefold, respectively. The oxide glass exhibited an increase of only ~50% after annealing under these same annealing conditions.

Data on fracture [4] for various oxynitride glasses indicate that the toughness increases slightly as nitrogen content increases up to ~8 eq. %. However, toughness values often change very little if at all with nitrogen content and then appear to depend more on the modifying cation and cation ratios. Thus, the compositional effects are more complex than simply determined by nitrogen content even though for some glasses the dependence on this factor appears to follow changes in the Young's moduli.

A related but quite remarkable effect is the fact that nitrogen additions clearly increase the resistance to slow-crack growth of these glasses. Three studies of Si–Y–Al glasses revealed that the addition of nitrogen shifts the range of slow-crack growth to significantly higher applied stress intensity ranges as compared to that for oxide glasses [4]. This effect can be attributed to a reduction in the fraction of threefold –Si–O ring structures when nitrogen is added, which are resistant to fracture in inert environments but fail readily in the presence of water. As compared to oxide glasses, the benefits of nitrogen-bearing glasses are that they exhibit longer lifetimes under fixed applied stress conditions and/or more limited reductions in strength when stressing rates are reduced.

5.5 Optical and Electrical Properties

Because of the higher ionic polarisability of nitrogen with respect to oxygen, the refractive index of Mg-, Ca-, Y-, and Ln–Si–Al–O–N glasses increases with increasing nitrogen at constant cation composition [1]. The modifying cation nonetheless plays a role in that the refractive index generally increases with the concentration of lanthanide cation and also with the ionic radius of the rare-earth cation [4].

When nitrogen substitutes for oxygen, IR transmission is significantly improved, whereas UV transmission is impaired because of impurities in the glass [1].

Studies of luminescence of Ce(III)–RE–Si–Al–O–N glasses revealed that 5d–4f emission shifts to longer wavelengths as the Ce ion content increases [19]. At low concentrations, Ce^{3+} displaces RE^{3+} ions (RE = Sc, Y, La, Gd) from large, more ionic sites in these glasses close to Al, yielding the short wavelength emission [4, 19].

Early studies of Y–Si–Al–O–N glasses showed increases in dc conductivity and low-temperature dielectric constants with N concentration, but these results were reported for glasses lacking systematic changes in

composition. Subsequent work [1] indicated that the dielectric constants of Mg-, Ca-, and Y–Si–Al–O–N glasses with fixed cation contents do increase with nitrogen levels.

6 Oxynitride Glass–Ceramics

Like other silicate glasses (Chapter 7.11), oxynitrides may be annealed at appropriate temperatures to form glass–ceramics. The crystalline phases formed depend on both the composition and heat treatment of the parent glass. The conventional process to produce a glass–ceramic involves two steps (Chapter 5.4): (i) a low-temperature heat treatment to induce nucleation followed by (ii) heating to a higher temperature to allow the growth of the crystalline nuclei. Usually glasses require the addition of a nucleating agent to promote the crystallization process [7] but oxynitride glasses are self-nucleating whenever the slightly reducing atmosphere used for their preparation causes the precipitation of FeSi particles on which heterogeneous nucleation then takes place.

Many studies of crystallization of oxynitride glasses have concentrated on the Y–Si–Al–O–N system. The glass–ceramic transformations in a glass of composition 28Y : 56Si : 16Al : 830 : 17 N were studied with both the “classical” two-stage glass–ceramic heat-treatment process outlined above and a differential thermal-analysis technique [20]. In the classical process, a series of heat treatments (below and above T_g) were carried out in a tube furnace to determine the optimum nucleation temperature that corresponds to the largest volume fraction of crystalline phase formed and the finest crystal size. The differential thermal analysis (DTA) method involves isothermal holds in the same temperature range as the classical method for a constant time at different nucleation temperatures, followed by heating at a constant rate up to the observation of the crystallization peak temperature. These two methods were found to be in close agreement [20]. Optimum nucleation and crystallization temperatures were determined in relation to the glass-transition temperature. The major crystalline phases present are mixtures of different forms of yttrium disilicate and silicon oxynitride. Bulk nucleation is the dominant nucleation mechanism. The activation energy for the crystallization process is 834 kJ/mol. In glasses with higher Al : Si ratios, as nitrogen content increases, gradual replacement of yttrium disilicate phase by yttrium aluminum garnet (YAG) is observed and nitrogen is mainly incorporated into Si_2N_2O .

A separate study [2] of crystallization of a glass with the 35Y : 45Si : 20Al composition containing 23 eq. % N allowed precipitation of B-phase (Y_2SiAlO_2N),

Iw-phase ($\text{Y}_2\text{Si}_3\text{Al}_2(\text{O},\text{N})_{10}$), and wollastonite (YSiO_2N) at temperatures below 1200°C whereas α -yttrium disilicate ($\text{Y}_2\text{Si}_2\text{O}_7$), apatite ($\text{Y}_2\text{Si}_3\text{O}_{12}\text{N}$), and YAG ($\text{Y}_3\text{Al}_2\text{O}_{12}$) formed at higher temperatures. At the relatively low temperatures of ~ 950 – 1100°C , the nucleation and growth of N-wollastonite (YSiO_2N) and of the intermediate phases B and Iw are kinetically favored over those of the more stable equilibrium phases YAG and $\text{Si}_2\text{N}_2\text{O}$. In the initial stages of crystallization of this glass, the creep rate is higher than for the parent glass since the residual glass following nucleation has a lower viscosity caused by a decrease in yttrium and an increase in impurity cations. After complete crystallization, however, the creep rate is very low. On a similar glass with 17 eq. % N, a double-stage glass–ceramic heat treatment (960°C for one hour and 1050°C for five hours) allowed crystal growth to form B-phase. A flexural strength of 550 MPa was measured for the glass–ceramic. This compares with many commercial glass–ceramics that have strength values in the range 120–350 MPa depending on composition and crystal morphology present.

7 Phosphorus Oxynitride Glasses

The chemical resistance, thermal, and optical properties of phosphate-based glasses (Chapter 7.9) can be improved through the introduction of nitrogen into their structure by cross-linking polymeric phosphate chains together in the glass network. As indicated by NMR analysis, nitrogen replaces oxygen in the phosphate glass network by bonding either to two phosphorus atoms (via one double bond and one single bond) or to three phosphorus atoms via three single bonds [21].

Because melts containing P_2O_5 and N are prone to decompose, processing of phosphorus oxynitride glasses is restricted to much lower temperatures ($<900^\circ\text{C}$) than for silicates. But Si-free phosphorus oxynitride glasses have been successfully produced by nitridation of alkaline or alkaline earth phosphate glass frits under anhydrous ammonia [22] or dissolution of metal nitrides into the melt. In these systems, nitridation reaches a stability limit at ~ 800 – 900°C . Above this range phosphorus is lost from the melt as a result of reduction from P^{V} to P^{III} and subsequent volatilization and reaction with atmospheric moisture to form phosphine, PH_3 .

Properties such as glass-transition temperature, dilatometric softening point, refractive index, viscosity, microhardness, and chemical durability all increase with increasing nitrogen content whereas thermal expansion coefficient decreases as in silicate-based oxynitride glasses [21, 22].

8 Lower-Temperature Preparation Methods

One of the major disadvantages to the use of oxynitride glasses for high stiffness/high hardness applications is the fact that melting at temperatures of the order of 1650 – 1700°C are required to achieve sufficiently low viscosities for glass pouring. Increased viscosities also mean that glass forming or drawing processes must be carried out at higher temperatures than are normal for conventional glasses. However, fluorine can be successfully substituted for oxygen at the same time as nitrogen [9]. The network-terminating effect of fluorine induces significant reductions in both glass melting temperatures and T_g /dilatometric softening temperatures. Despite these decreases, elastic modulus and hardness are virtually unaffected by fluorine substitution. This latest extension of oxynitride glass development may facilitate exploitation of the excellent stiffness and hardness characteristics of these glasses, thanks to their lower processing temperatures.

9 Perspectives

Oxynitride glasses are a group of specialty glasses with superior properties to their oxide glass counterparts, one of a range of “new” glasses with novel functions that are being developed for potential technological applications. Their mechanical, rheological, and optical properties can be tailored by changes in their composition, especially nitrogen content and also various alkaline-earth or rare-earth-modifying ions.

There are still significant challenges in developing oxynitride glasses for use in optical applications. In order to develop optically transparent glasses, a more fundamental understanding of the reactions occurring during synthesis and the mechanisms involved in the formation of such glasses is required along with development of methods for eliminating impurities in the final product such as elemental silicon and silicides. However, because of their lower densities, these glasses are now being investigated as potential materials for use in more lightweight applications in modern communications equipment, in biomedical devices, and where reductions in energy usage are critical. In view of their superior durability, higher stiffness, higher hardness, higher softening points, and tailored thermal properties, oxynitride glasses may find use in various “nonoptical” applications.

These novel applications of oxynitride glasses include passive coatings on electronic substrates using their higher dielectric constants and elastic moduli to best

advantage; special windows for aerospace applications where their higher elastic moduli would allow them to remain stiff in thinner sections, thus allowing weight and energy savings; new bioactive oxynitride glasses and glass–ceramics with better load-bearing properties; glass-decoration enamels using the color effects found in Ln–Si–Al–O–N glasses; glaze systems for refractory protection taking advantage of their higher viscosities; joining of silicon nitride-based ceramics and of these ceramics to metals, where the grain boundary glasses are similar in composition to the bulk glasses; higher-temperature range glass–ceramics for structural applications where their higher refractoriness would make them more stable at higher service temperatures.

So far, oxynitride glasses have not found any major commercial uses. The gains in properties are not significant enough to compensate for the increased production costs arising from the more difficult manufacturing processes involved, which require controlled nitrogen atmospheres at temperatures of 1650–1700 °C. In order to make a significant breakthrough in terms of commercial glass products, the major challenge that needs to be addressed is the development of more cost-efficient and up-scalable synthesis methods. Some companies have confidential ongoing programmes to investigate these possibilities.

One solution that would allow melting temperatures to be reduced is the substitution of oxygen by both fluorine and nitrogen. The higher elastic modulus and hardness conferred by nitrogen is maintained which might allow exploitation in some of the specialist applications outlined above.

Phosphate Glasses

Andrew James Parsons

Faculty of Engineering, University of Nottingham, University Park, Nottingham, UK

1 Introduction

Phosphorus was an unintended by-product of alchemical speculations. Searching for the philosophical stone (Chapter 10.10) in human urine, Hennig Brand (seventeenth century) ended up toward 1669 isolating the new element from the *microcosmic* salt $[\text{Na}(\text{NH}_4)\text{HPO}_4]$ and termed it *light bearer* (*phosphoros*, in Greek, the name also given to the planet Venus) because of the glow caused by its slow, spontaneous combustion. Thanks to this most unusual property, phosphorus aroused considerable attention before giving progressively rise to a rich chemistry. Polyphosphates were, for instance, first synthesized by Jacob Berzelius (1779–1849) in 1816 as an ignition product of orthophosphoric acid. Phosphate glasses are a subgroup of polyphosphates. One of them is the well-known Graham's salt, which was produced in 1833 [1] by fusion of sodium hydrogen phosphate (NaH_2PO_4), which induces dehydration reactions yielding first $\text{Na}_2\text{H}_2\text{P}_2\text{O}_7$ and then $(\text{NaPO}_3)_6$. In 1848, Fleitmann and Hennenberg then pointed out that this substance was most likely a mixture of polyphosphates with different chain lengths.

Because of the limitations of purification methods, however, a century elapsed before the structure and chemistry of these substances could be properly studied. Molecular weight separation by paper chromatography was then a key advance as particularly well illustrated by Van Wazer in his 16-part series on the structure and properties of condensed phosphates [2]. Crystallography provided in the 1940s the first insights into P–O bond distances in isolated crystals. Not surprisingly, much progress has been made since then on both

crystalline and glass phases, thanks to modern characterization methods.

Phosphate glasses were first applied to mineral analysis and water softening. Interest in optical applications was raised at the very beginning of the twentieth century but vulnerability to moisture was problematic. Very broad spectral windows from the ultraviolet (UV) to the near infrared (IR) was so much an asset, however, that water-stable compositions were devised in the 1940s [3]. Building on the work of Van Wazer and his contemporaries in the 1950s, development of solid-state lasers took place in the 1960s after it had been discovered that these glasses could take up large amounts of rare earth elements. This affinity for rare earths led them to be used also for nuclear waste containment in the 1970s (Chapter 9.11). As for the vulnerability to water, it has recently been turned into a benefit in absorbable medical devices and in controlled delivery of trace elements. Last but not least, interesting electrical properties have sparked research into the use of phosphate glasses in dielectrics, semiconductors, and fast-ion conductors.

In this chapter, the structure of phosphate glasses will first be described in terms of the speciation of PO_4 groups and the length of phosphate chains. Next, the synthesis of these glasses and the problems raised by their affinity for water and by their corrosivity will be summarized. Practical applications will then be reviewed. Their extent is not readily ascertained because the vitreous nature of products is not always indicated. The nearly a thousand patents filed since 1926 nonetheless gives an idea of their variety. Specific values of tonnage production per year are difficult to find, though several hundred thousand tonnes of calcium magnesium phosphate glass are produced as a fertilizer in Asia and South America [4]. The most conspicuous use is in optical systems, but the ability to control the exchange of ions with phosphate glasses is at the roots of less visible, but much more common

Reviewers: R.K. Brow, Materials Science and Engineering, Missouri S&T, Rolla, MO, USA
U. Hoppe, Institute of Physics, Rostock University, Rostock, Germany

applications. Only the main ones will be dealt with here. Many others are described in the literature [2, 5–7].

2 Structure

2.1 Phosphate Groups

Condensed phosphates consist of corner-to-corner connected tetrahedral PO_4 groups forming chains and networks (cf. [8, 9] for more detailed information). There are no edge or face connections, which would give rise to highly stressed cyclic groups. Although phosphate chains are flexible, the P–O bond length average is remarkably constant at about 1.54 Å, with internal bond angles of 110–120° and intra-tetrahedral angles of 125–155° [3, 10]. Through charge repulsion, chains of 5–10 tetrahedra are typically straight, but increase in flexibility as length increases beyond 10. The greatest degree of freedom results from bond rotation, which allows for a great variety of conformations as illustrated by the Rubik's snake toy.

The phosphate groups in a chain or network structure are described in terms of Q^n species where n indicates the number of bridging oxygens in a tetrahedron (Figure 1). With respect to silicates (Chapter 2.4), the difference is that the 5+ nominal charge of P requires an extra P–O bond, which translates into a double bond in Q^3 species only because resonances make all nonbonding P groups equivalent in the others. Among glass formers, phosphates perhaps show the closest structural similarity to organic polymers (Chapter 8.8) because of the great many different ways in which Q^n species can form a networked or cross-linked structure with chains of different lengths. This is why they have been referred to as *inorganic polymers* [11].

It is useful to distinguish these different structures with the nomenclature used by Graham for polyphosphoric acids, namely

Orthophosphoric acid	3 H_2O :1 P_2O_5	$\sim \text{H}_3\text{PO}_4$
Pyrophosphoric acid	2 H_2O :1 P_2O_5	$\sim \text{H}_4\text{P}_2\text{O}_7$
Metaphosphoric acid	1 H_2O :1 P_2O_5	$\sim \text{HPO}_3$

In terms of Q^n speciation, orthophosphates thus represent isolated Q^0 , pyrophosphates Q^1 dimers, and metaphosphates Q^2 chains, where H_2O can be replaced by

other modifier oxides, M_2O . When the ratio of modifier to P_2O_5 falls below 1 : 1, i.e. for more than 50% P_2O_5 , Q^3 cross-links begin to form and create what Kroll called in 1912 an *ultraphosphate*. Recently, glasses between pyrophosphate and orthophosphate have become known as an *invert* (Chapter 10.11), because their properties are dominated by the modifiers rather than by the glass formers. They are also referred to as *ionic polymers* as they represent effectively a series of linked anions and cations without a covalent glass network. The ratio $\text{M}_2\text{O}/\text{P}_2\text{O}_5$ is generally denoted as R . The ortho-, pyro-, and metaphosphates thus refer to R values of 3, 2, and 1, respectively. In between them, one then finds invert glasses/ionic polymers (3–2), poly-(2–1), and ultraphosphates (1–0), respectively.

Any chain must of course have two ends, such that a linear metaphosphate could only exist as an infinitely long chain. Metaphosphates have in fact cyclic structures that have been observed with up to eight units; larger cycles likely exist but have not been isolated yet. With up to 10^6 units, the effect of end groups of course becomes vanishingly small, which is why chains can generally be referred to as metaphosphates although they should really be described as polyphosphates.

As justified by Van Wazer [2], the general structure of phosphates can be described by the formula:

$$\text{M}_{nR}\text{P}_n\text{O}_{n(5+R)/2}, \quad (1)$$

where n is the number of P atoms and nR and $n(5+R)/2$ must also be integers. The special cases of zero and unity values for R thus refer to P_2O_5 and MPO, respectively. A simple relationship then yields the theoretical phosphate chain length from the ratio R as:

$$n = 2/(R - 1). \quad (2)$$

Taking $R = 1.5$ as an example, one obtains $n = 4$ and, thus, the formula $\text{M}_4\text{P}_4\text{O}_{13}$. This relationship is very useful when manufacturing phosphate glasses to achieve a particular structure even though the value obtained is an average. It refers to a distribution whose width depends on the degree of homogenization of the glass, the nature of the modifiers, and the actual water content since H_2O can be considered as a modifier oxide.

The chain length of polyphosphates changes exponentially with the modifier content when R tends to unity (Figure 2) so that n , for instance, increases from 100 to

Figure 1 The Q^n speciation of phosphate groups. Resonances indicated by dotted lines, making nonbonding P groups equivalent in all but Q^3 species. Q^0 species are actually relatively unusual.

Figure 2 Exponential increase in the theoretical chain length of phosphates (n) as a result of changes in the modifier to former ratio (R) according to Eq. (2). Equivalences of O/P and R ratios shown for 3 values of R .

200 when R changes from 1.02 to 1.01. Hence, great care must be taken when making glasses close to the metaphosphate as small variations in formulation and manufacturing conditions can have a big impact on the final result.

A further simplification obtains when considering just the oxygen–phosphorus ratio, O/P . This ratio is helpful in complex glasses with multiple modifiers, particularly those found in different oxidation states. Like R , the O/P ratio reduces to simple values for single Q group types, namely 4, 3.5, and 3 for ortho-, pyro-, and metaphosphate, respectively.

2.2 Mixed Glass Networks

Hybrid glass types are obtained when phosphates are mixed with other oxide glass formers. For the sake of comprehensiveness, it is useful to mention them briefly although these materials are beyond the scope of this chapter. Borophosphates form readily upon melting of boric anhydride and phosphate salts because boron can accept an electron pair and phosphorus can donate one. The $B-O-P$ linkages created between the borate and phosphate units increase the overall connectivity of the network in a way reminiscent of the 3-D open structure of SiO_2 . The great affinity between boron and phosphorus in glasses is reflected by vapor pressures that remain so small above $1000^\circ C$ for a simple borophosphate (BPO_4) [12] that the rate of vaporization remains negligible up to $1450^\circ C$ [2]. The contrast is thus striking with borosilicates or borates for which boron loss can be significant below $1000^\circ C$.

Between SiO_2 and P_2O_5 the structural match is not so good. A phosphate glass typically incorporates up to

about 12 wt % SiO_2 before crystallization occurs, whereas the phosphate solubility in silicates is limited to about 6 wt % P_2O_5 , the insertion of PO_4 tetrahedra into the SiO_4 network normally requiring the association of P^{5+} with charge-balancing cations [13]. As a matter of fact, $Si-O-P$ linkages are not very stable so that they are readily hydrolyzed in water. This intrinsic weakness is turned to an important advantage in bioglasses since phosphosilicates represent a readily available source of PO_4^{3-} ions in solution to contribute to the formation of hydroxyapatite (Chapter 8.4).

Aluminophosphates are also well known. Crystalline $AlPO_4$, which is isostructural with SiO_2 , exemplifies the stability of the $Al-O-P$ linkages also existing in aluminophosphate glasses. Even small additions of Al to a phosphate glass can in fact have a significant effect on properties [14]. Phosphate has also been combined with a wider variety of other formers to make glasses that include sulphur, arsenic, vanadium, or molybdenum.

2.3 Chain Lengths

Initially, simple chemical tests were used to establish that a substance is a polyphosphate, as opposed to a phosphate, such as the ability to coagulate albumen or to react specifically with silver, copper, or zinc. As already noted, however, real advances have resulted from the possibility to isolate specific polyphosphate species first by ultracentrifugation and solubility fractionation and, more efficiently, by 2-D paper chromatography [7]. Resolution of phosphate chains up to 200 units was then made with gel electrophoresis before a wealth of other chromatographic and spectroscopic methods became available.

An important goal of structural studies is the determination of chain lengths. An early method relied on acidity differences between OH groups, depending on the Q^n species to which they belong, namely Q^2 (1 OH, strong acid) or Q^1 (2 OH, one weak and one strong acid). From usual titration curves, it was possible to determine the numbers of strong and weak acid groups and, in particular, to distinguish between cyclic and linear polyphosphates because the former includes only the strong acid groups of Q^2 species. In this way, Graham's salt appeared to be a mixture of linear polyphosphate chains. Other methods to quantifying chain length included solution viscosity, conductivity, and light scattering measurements. Of particular note was the application of the relatively new nuclear magnetic resonance (NMR) spectroscopy by Van Wazer in 1955 [2, 3], which proved to be simpler and more accurate than the end-titration method.

The drawback of these approaches was that they relied on solution techniques. These were fine for sodium polyphosphate glass initially studied, which dissolves very

rapidly in aqueous solutions. For more complex phosphate glasses, however, the rates of dissolution can be extremely low and the temperature or pH changes made to increase them also cause chain hydrolysis, therefore invalidating the measurement. This is why measurements are now directly performed on glasses with a variety of solid-state techniques (Chapter 2.2).

Phosphorus lends itself very well to NMR because ^{31}P provides good signal resolution in a relatively short time. Like for silicates, MAS spectra can provide quantitative information on Q^n speciation (Figure 3) [15] whereas evidence for the interaction of these species is directly drawn from 2-D spectra. Raman spectroscopy can similarly provide information on the ratio of Q species whereas bond lengths and angles as well as coordination numbers are determined with X-ray and neutron diffraction techniques although the complex spectra obtained for glasses with multiple different modifiers quickly become challenging to interpret. In this respect, the availability of a wealth of such data for crystalline phosphates [10] is of great help as a reference framework for the interpretation of glass structures.

3 Synthesis

3.1 Composition Ranges

By usual melt cooling, glasses based on P–O–P networks can be prepared in very wide composition ranges. A number of modifiers and intermediates have been incorporated for P_2O_5 contents ranging generally from ~35 and 65 mol %. They include Li, Na, K, Mg, Ca, Sr,

Ba, Ti, Cr, W, Mo, Cu, Zn, Al, Sn, Fe, Mn, Co, Ag, La, Yb, Nd, Er, or Pb in a list that is by no means exhaustive.

The simplest orthophosphoric acid (H_3PO_4) supercools to form a glass with an unusually low T_g of -121°C [12]. In polyphosphoric acid, where $\text{M}_2\text{O} = \text{H}_2\text{O}$, hydrogen bonds contribute to glass formation. These glasses are model viscoelastic liquids at room temperature where their relatively low viscosities of 10^7 – 10^8 Pa.s make them flow slowly but shatter instead if struck. When water is (largely) replaced by metal oxides, phosphate glasses can exist from pure P_2O_5 to the invert domain provided that the correct modifiers and manufacturing conditions are used. Without very rapid cooling, however, the limit of vitrifiability of about $R = 5/3$ (tripolyphosphate) varies somewhat with the modifier. Whereas 64 mol % can be included for ZnO and 57 mol % CaO [5], the maximum content of K_2O is only 47 mol % beyond which potassium Kurrol's salt $[(\text{KPO}_3)_x]$ crystallizes readily. Upon rapid cooling, these modifier contents can be increased, for example, up to more than 80 mol % ZnO with splat quenching.

3.2 Synthesis

In the laboratory, phosphate glasses are usually synthesized from phosphate salts whose stoichiometry is balanced by P_2O_5 or $\text{NH}_4\text{H}_2\text{PO}_4$ for increasing the phosphate fraction and by metal oxides, carbonates, or hydroxides for raising modifier contents. Some care must be taken in selecting precursors as P_2O_5 reacts exothermically with all basic oxides, sometimes explosively.

Figure 3 Changes of Q^n speciation as a function of composition apparent in ^{31}P solid-state NMR spectra. Glass compositions (mol %): A = 40 P_2O_5 ·24 MgO·16 CaO·20 Na_2O ; B = 45 P_2O_5 ·24 MgO·16 CaO·15 Na_2O ; C = 50 P_2O_5 ·24 MgO·16 CaO·10 Na_2O . Approximate ppm ranges where the different Q groups occur are indicated by the brackets on the x axis.

The starting mix is heated to temperatures typically higher than 650 °C, sometimes as high as 1400 °C, to trigger condensation reactions whereby polyphosphate chains form and water is expelled as a gas. The reaction of sodium phosphate is for example:

It is of course idealized since NaPO_3 would denote a polyphosphate chain of an infinite length. The length depends on melt composition and is limited by the fact that the developing structure makes it more difficult for water to escape. Its removal can be enhanced by low H_2O partial pressures above the melt, long melting times, or repeated *freezing out*, i.e. alternate crystallization and melting steps, but there is in practice a chain length limit of a few hundred phosphate units. The effects of water are so pronounced that the idea of using different melt times (and thereby having different amounts of entrapped water in the final glass) to differentiate properties was patented. Some speciality glass producers reduce final water levels by utilizing premade polyphosphate salts in their batches, thereby avoiding water that is generated as a result of condensation reactions between simple orthophosphate salts during melting.

The problem of water notwithstanding, phosphate melts are very easy to produce. Fast melting and refining is made possible by their comparatively low viscosities and the fact that they absorb heat rapidly: 90% of incoming radiation at wavelengths higher than 2.5 μm is absorbed within the first $\sim 0.01 \text{ mm}$ of the melt [2]. But precise compositions can be difficult to achieve because of the volatilization of some components. Hence, processing temperatures must be kept low wherever possible to avoid losses that could reach a few % [16] and also depend on phosphate content, type of modifier, and humidity.

An alternative approach to which attention has recently been paid relies on sol–gel wet chemistry (Chapter 8.2). Here, the multistage reaction involves an organophosphate precursor like triethyl phosphate $[(\text{C}_2\text{H}_5)_3\text{PO}_4]$ and an organometallic compound such as calcium methoxide $[\text{Ca}(\text{OCH}_3)_2]$. The advantages are first those of a room-temperature process not needing platinumware and, second, the production of glasses that cannot be obtained from melts (e.g. compositions with extremely low phosphate contents). As for the drawbacks, they are the use of toxic and costly chemicals as well as scale limitations caused by the considerable shrinking of gels upon drying.

3.3 Corrosivity

A particular difficulty in producing phosphate glasses is that their melts are so corrosive that they have been described as *universal solvents* [6]. This feature has stood

them in good stead in applications such as mineral analysis but otherwise causes manufacturing problems. Most ceramics are attacked by phosphate melts, in particular by surface-tension erosion, which implies that the composition of the final glass can be drastically altered by material dissolved from the container. A striking example is that of a sodium phosphate glass, which takes up more than 30 mol % Al_2O_3 when melted in a fused alumina crucible [14]. Quartz is corroded by phosphoric acid itself so that SiO_2 crucibles are also liable to attack from a phosphate melt. Graphite can be an alternative but significant phosphate reduction becomes likely above 350 °C, affecting the structure of the glass and giving it a pinkish hue. Since phosphate melts require an oxidizing environment, graphite is in addition limited by its own oxidation at higher temperatures. Despite such corrosion problems, cost benefits make ceramic melting pots still used for manufacture but great care is taken to record how much container material is incorporated in the melt.

The most resilient materials for handling phosphate melts are noble metals and their alloys. Platinum is good for resisting basic melts, whereas gold fares better for high P_2O_5 formulations. A particular benefit of gold-platinum alloys is their low wetting properties, which reduce the chance of surface-tension-driven corrosion. Platinum alloys can suffer a slight corrosion above 300 °C, however, whose extent decreases with decreasing surface-to-volume ratios. In all cases, an oxidizing atmosphere is needed and contaminants that might cause phosphate reduction must be avoided, since they can result in the formation of platinum phosphides at grain boundaries in the alloy. Because small amounts of contaminants can create significant damage, crucibles must be placed only on clean ceramics. The SiC plates often used in furnaces must be avoided, however, because Si forms a eutectic with platinum so that local alloying could trigger melting of the crucible at a temperature as low as 830 °C.

The potential for electrical circuits involving a melt can also be a source of damage, which is of importance in glass fiber production facilities that use electrically heated bushings. The platinum alloy fiber bushings are cast within an insulation material, which is then placed into a steel housing to support the weight. Ordinarily, the steel box is electrically isolated from the heating system to prevent galvanic corrosion. However, phosphate melts are very good at wetting platinum alloys and can dissolve insulation materials so over time the melt can travel up the bushing tips, across the base plate and insulation and make electrical contact between the busing and the steel housing. The steel is preferentially oxidized as it has a lower anodic index than the platinum. However, this results in phosphate within the melt being reduced, which can then attack the platinum, with subsequent phosphide deposition as previously described.

Corrosion is at its worst at the beginning of the polycondensation reaction when the structure is forming and water is expelled. After this first step, the melt is less aggressive on the container, likely because of a decreased driving force for modifier uptake. Ultraphosphates are bad at ion sequestering, which seems to make them less corrosive but their water sensitivity may require that they be melted in sealed ampoules. The best container for phosphate melts is actually the solid form of the phosphate of interest. Centrally heated furnaces can thus be designed with cooled skins such that the molten phosphate reacts within a chilled skin of the same material as done in a Pochet furnace. With industrial processes, purer phosphate glasses are made in this way than with small-scale laboratory methods.

4 Physical Properties

4.1 The Importance of Field Strength

The effect of modifiers on physical properties depends on their field strength (as described by Dietzel). Higher valences and smaller ions yield stronger P–O–M linkages and, therefore, more significant effects on properties. When only low field-strength modifiers such as Na or K are present, P–O–M bonding is thus weak and glass properties tend to be dominated by polyphosphate chains. With high field-strength modifiers (e.g. Fe, Ti), the reverse holds true because of stronger P–O–M linkages. The crystallization rate is, for example, greatly affected by chain length, whereas the dissolution rate depends heavily on modifiers. A *mixed modifier* effect (–Chapter 4.6) is also known whereby transport properties of glasses with equivalent content of modifiers of the same valence show minimum or maximum values.

4.2 Rheological and Related Properties

Rheological properties are related to the mobility of the glass structure, which depends itself on the chain length of the glass network and the nature of modifiers. With weak P–O–M linkages, the mobility mainly decreases because the phosphate chains become longer, with a resultant modest rise in glass transition and crystallization (T_x) temperatures as well as in viscosity as observed in organic polymers (Chapter 8.8). Above 50 mol % P_2O_5 a network begins to form, which causes a drop in T_g but a significant increase in viscosity. These properties are greatly affected when the structure includes modifiers that create strong P–O–M linkages so that T_g and T_x increase by several hundred degrees. This increase tends to follow a linear trend with modifier content (Figure 4). But certain modifiers exhibit more unusual properties,

Zn- and Sn-bearing compositions having, for example, comparatively low T_g values and viscosities. Typical examples of T_g for a range of binary glasses are provided in Table 1.

Phosphates are Newtonian and generally fragile melts (Chapter 4.1). Their low viscosity makes them prone to crystallization, especially when chains are short. As usual (Chapter 4.1), addition of strong modifiers can increase viscosity by orders of magnitude near the glass transition but this effect diminishes at high temperatures [40] (Figure 5).

A simple indicator of the resistance to crystallization is the difference between T_g and the temperature of the onset of crystallization. The rate of crystallization decreases with increasing configurational entropy because a large number of modifiers make rearrangements of the glass into a crystalline structure more difficult. As a simple example, glass formation can be easier when calcium and magnesium coexist than if only one or the other is present at a lower overall content. In contrast, long chains do not prevent Kurrol's salt from crystallizing from sodium polyphosphate because, with a single modifier type, these chains are equivalent and can thus assemble easily into a repeating crystal structure. Of course, chain length is nonetheless important as indicated by the fact that chains with 6–200 phosphate units usually do not crystallize.

4.3 Volume Properties

With weak modifiers, the glass density decreases as the phosphate content increases and longer chains become more difficult to pack, but it increases as the composition approaches pure P_2O_5 . In contrast, the density generally increases at constant P_2O_5 content when replacing a weak modifier with a strong one (e.g. replacing Na with Ca). The effect is linear, similar to those seen with T_g . At a microscopic level, increasing the electron density in modifiers creates a denser structure through shorter M–O distances but does not cause a change in the average P–O bond distance [8]. The effects of chain length and modifier strength on density are thus opposite, but the latter generally predominates.

Phosphate glasses have comparatively high thermal expansion coefficients (CTE, see Table 1 for some examples) with high values such as the $22 \times 10^{-6} \text{ K}^{-1}$ of the 63.7 P_2O_5 ·9.1 ZnO·24.8 K_2O ·2.4 Al_2O_3 glass of the US patent 3 407 091 [43]. Upon manufacture, such high values can result in significant negative hoop stress, and subsequent deformation, if melts are allowed to cool in crucibles. Annealing is of course required to eliminate residual stress, but phosphates differ from silicates in this respect in two ways. They need to be heated to $\sim 10^\circ \text{C}$ above their dilatometric softening points for effective annealing [5]

Figure 4 The dramatic effect of strong modifiers on glass transition temperature (T_g), as measured by differential scanning calorimetry. Substitution of 12.5 mol % Al_2O_3 or 15 mol % Fe_2O_3 having almost as much effect on T_g as 40 mol % CaO . Average T_g values for binary glasses from Table 1 and trend data from Ahmed [37], Brow [38] and Parsons [39].

Table 1 Example thermal and optical properties of binary phosphate glasses.

Nominal composition	T_g (°C)	Density (g/cm ³)	CTE (10 ⁻⁶ K ⁻¹)	RI
50 Li ₂ O 50 P ₂ O ₅	322–335	2.35		1.51

and they also require post-annealing cooling rates about twice slower probably because of aging processes of chain structures analogous to those of organic polymers (Chapter 8.7).

5 Optical Properties

5.1 Classical Optics

Phosphate glasses have refractive indices similar to those of silicate glasses but a lower dispersion that places them on the lower left of the Abbe diagram (Figure 6). Because of poor water resistance, their first optical applications made at the end of the nineteenth century by Schott in terms of crown and filter glass did not initially fare well [44]. But a superior UV transmission motivated further research such that Corning filed a patent in 1926 for its UV transmitting Corex glass, containing Al, Ba, and K, before moisture resistance was largely achieved by the 1940s [3]. Glasses produced in 1940 then absorbed both UV and IR light, while transmitting visible radiation, whereas inclusion of iron resulted in windows very effective at absorbing heat. By appropriate formulation of phosphate (and fluorophosphates) glasses, it is now

possible to produce spectral filters for a very wide range of wavelengths between about 200 and 1000 nm. Borophosphates also proved interesting in optics as they provide high wetting surfaces, which means that water forms on lenses as a transparent film instead of discrete fogging droplets.

5.2 Rare-earth Doping

Phosphate glasses have filled a particular niche, thanks to the large amounts of rare earths they can incorporate without clustering, which would result in the inactivation of these ions. Whereas silicates can be doped with only a few hundred ppm of rare earths before the occurrence of such a *concentration quenching*, phosphates can contain several percent. As illustrated, glasses bear 18 mol % Er_2O_3 [45]. Such large concentrations of rare earth enables phosphate glasses to be used in fiber amplifiers that are only a few cm long instead of the 20 m of fiber required by silicate glasses (Chapter 6.4). Optical-fiber amplifiers are in development for broadband systems with high-gain, short devices providing on the order of 4.1 dB in only 3 mm [46].

High levels of doping, large emission cross sections, low nonlinear dispersion, low pump thresholds, and

Figure 6 Abbe diagram for a range of different glass types (Chapter 6.1), based on the Schott Glass catalogue. Phosphate crown glasses toward the lower left.

reasonable thermal stability have fostered the extensive use of phosphate glasses in solid-state lasers since the 1970s, initially with Nd [47], then with Er in the 1980s, and more recently with Yb. The glass compositions tend to have more than 50 mol % P_2O_5 to widen the UV range of transparency.

5.3 Laser Systems

Neodymium-doped phosphate is the most common laser glass in use, with the most widely used commercial glasses being LG-750, LHG-8, LG-770, and N31. Nd has four available transitions, with the one of the greatest interest being the ${}^4\text{F}_{3/2} \Rightarrow {}^4\text{I}_{11/2}$ at 1050–1060 nm. Large Nd phosphate laser systems have been used in a number of laser ignition facilities around the world, including GEKKO-XII in Japan, Shen Guang III in China, the Mégajoule Laser Project (LMJ) in France, and the National Ignition Facility (NIF) in the United States. These facilities use extremely high-energy lasers to heat tiny fuel containers in attempts to create nuclear fusion and understand better the mechanisms of nuclear explosions. The laser power of NIF is, for example, 500 TW as reached with 192 beam lines in a parallel system with a total path length of around 1500 m. The 1.85 MJ energy generated within picoseconds yields pressures of 300 billion atmospheres.

Since then the development of silica/phosphate combined laser systems has made reaching powers of the order of 10^{15} W (PW) possible. In 2015, a record high power of 2 PW for 1 ps has been reached in Japan at

FIREX-I, which represented 1000 times the world's total electricity consumption during this very short time frame.

The military is of course interested in laser systems as exemplified by the famous Strategic Defence Initiative (SDI) or *Star wars* program in the United States in the 1980s. With Nd phosphate glass laser, defense technologies have continued to be developed in ground-based systems. A truck-mounted 60 kW laser has been tested recently, although technology has moved toward single-crystal systems that are more robust physically.

In medical and rangefinder applications, Er has been used to produce *eye-safe* laser systems operating at around $1.5 \mu\text{m}$ (${}^4\text{I}_{13/2} \Rightarrow {}^4\text{I}_{15/2}$ transition at 1.53–1.6 μm , depending on host glass composition). Also, spectral glasses have been designed to filter out harmful laser wavelengths. Phosphate laser glasses are produced by companies including Schott (Germany), Hoya (Japan), Kigre (US), and SIOM (China).

Before 1990, the presence of platinum inclusions picked up during the manufacture of phosphate glasses has limited laser size because of damage caused at high peak power, which was eventually making the device unusable and could even affect other components in the optical pathway. Oxidative gas treatments are used to promote their dissolution, generally by bubbling through the melt oxygen or a mixture of oxygen and Cl-containing gases such as CCl_4 or POCl_3 . In this manner, Pt inclusions in phosphate laser glasses are practically eliminated, being fewer than 1 for 10 l of glass. The treatment is also effective at reducing water content, particularly when chlorine is used as it provides favorable

Figure 7 Continuously produced bars of phosphate glass highly doped with neodymium for use in laser cavities at the U.S. National Ignition Facility. Source: Photo public domain U.S. Department of Energy.

equilibrium conditions [48]. As a result, extremely large laser cavities can now be made by continuous processes (Figure 7), whereas surface ion exchange similar to the Gorilla Glass process (e.g. immersion in a KNO_3 melt to exchange small ions on the surface with large potassium ions and thereby creating a compressive surface) has improved two or three times the thermal-shock resistance.

5.4 Phosphate Glass Fibers

In contrast, the use of phosphate glasses as fibers is limited because their *fragile* rheology and high tendency to crystallize make them very difficult to draw. Silicate solutions for optical fibers thus remain preferred, all the more so that phosphates are difficult to integrate into existing infrastructures because of their higher expansivity. Monsanto saw potential in the use of crystalline phosphate fibers in a wide range of nonoptical applications, but this effort was cut short by concerns about environmental impact [6]. Since interest has increased in deliberately degradable fibers for applications such as healthcare, however, facilities for producing phosphate glass fibers have been developed [49]. Phosphate fiber tows and textiles are now produced by the Sinoma company (CN105819697).

5.5 Phosphors

Simplistically, phosphors are solid materials that absorb a particular wavelength of light and then, through radiative

and non-radiative relaxation, emit light at a different wavelength. Such a phenomenon is called photoluminescence. Depending on the material that the phosphor is made from, only specific wavelengths can be absorbed and only specific wavelengths emitted, depending on the band gap structure (Chapter 6.3).

Frequently, this is the conversion of UV to visible light (as is the case with the domestic fluorescent tube). Phosphors have been known since at least the early seventeenth century. An early example was the *Bolognian stone*, a luminescent stone with a BaSO_4 matrix. They have been extremely important in the lighting industry since Becquerel's Geissler tube in 1859 and then Edison's tungsten phosphor electric lamp in 1896. After the end of the Second World War and the advent of equipment for producing UV rays, a dramatic evolution in phosphors occurred, supported by advances in solid-state physics and the understanding of the spectroscopy of solids. The theory of excitation energy transfer and energy levels was clarified through crystal field theory and it became possible to make precise measurements of the multiple close energy levels in trivalent rare earth ions.

The 1940s and 1950s saw the use of manganese, antimony, and tin as phosphors in both silicate and phosphate matrices (the $3(\text{Ca},\text{Sr},\text{Ba})_3(\text{PO}_4)_2 \cdot (\text{Ca},\text{Sr},\text{Ba})\text{X}_2$: $\text{Sb}^{3+}, \text{Mn}^{2+}$ white light phosphor being of particular importance). The era of rare earths (initially Europium) began in the late 60s and early 70s and gave phosphors with very high color-rendering index and luminous flux. The development of better and better phosphors was of course concomitant with the rise of the color television. Phosphates have proved to be good phosphor host candidates, thanks to their low cost, good stability, broad UV transparency, and their range of crystal structures (control of which can shift emission wavelengths, for example, KSrPO_4 doped with Eu^{2+} shows blue emission, while in NaCaPO_4 , it is green). They also are good candidates for the development of strong red emitting phosphors, though current examples of which have low quantum efficiency [50].

The majority of phosphor materials are crystalline powders that are adhered to glass substrates, almost exclusively silicates. Glass has proved to be a very useful substrate, providing both an easily formed shape and the ability to create sealed vacuum vessels, but it has not been greatly used as the host for the emitting species. This is perhaps partially due to the limitations of inclusions possible in silicates, as discussed in Section 5.2. Conversely, phosphate glasses can contain large amounts of dopants without clustering issues, which has contributed to the development of glassy phosphate matrix phosphors.

Early phosphate glass works used similar elements to the crystal phosphors, such as manganese to produce

orange/red light emitting phosphors in zinc phosphate glass hosts [51]. The 70s and 80s brought some analysis of the rare earths but despite the successes of phosphate glasses in laser systems, glassy phosphate phosphors for lighting applications did not see significant research until the mid-2000s. The timing of this is likely related to the breakthrough in solid-state lighting technology that was the bright blue LED, produced by the Nichia Corporation in 1993. By coating this LED with a phosphor that shifted some of the wavelength to yellow, a bright white solid state light was achieved. These offered very high efficiency lighting without the need for mercury vapor. The development of appropriate triphosphors also enabled the use of UV LEDs to produce white light.

Now, phosphates glasses are being considered for white light LED lighting. They make use of the unusually low glass transition temperatures of zinc and tin phosphate glasses to form coatings on LEDs. This replaces the previous materials (usually organic polymers or silicones) and provides better heat resistance, which becomes important in higher powered LEDs. They also offer much simpler production processes, without the need to create crystal powders and adhere them to substrates.

Several glassy phosphate phosphors have been produced with different mixtures of rare earth elements. The combination of the colors produced by these additives (e.g. Dysprosium – blue, Terbium – green, Europium – red) provides white light when excited by UV. Some examples are listed in Table 2. However, with the increasing pressure on rare earth resources and their very localized areas of production, recent papers are looking to revive non-rare earth white light

phosphors by returning to the historical Sb^{3+} , Mn^{2+} systems [52].

As well as the more conventional UV light activated materials, systems have been produced for heat sensing applications whereby IR radiation is converted to visible light [59]. Further, there are ytterbium phosphate glass phosphors capable of converting UV radiation into IR radiation [60], with potential for use in solar cells or in heating.

5.6 Electromagnetic Safety

Some other applications are related to the nuclear industry where lead tungsten phosphate glasses were developed in the 1950s as X- and γ -ray absorbing windows. A particularly neat radiation safety application is the use of silver phosphate dosimeters, produced by the Chiyoda company. Although silver is readily reduced into the metallic state in silicates, it is possible to incorporate 10% Ag_2O into phosphate glasses without problem. If a silver phosphate glass is exposed to γ -rays and then to UV light, the intensity of the visible light emitted is proportional to the γ dose received.

6 Chemical Properties

6.1 Dissolution Mechanisms

As is well known in silicates, dissolution of glass usually occurs through several mechanisms in combination such as hydration, hydrolysis, and ion exchange/

Table 2 Examples of phosphate glass phosphors.

selective leaching (Chapters 5.11 and 5.12). The same holds true for phosphates but the mechanisms are quite different. In silicates, the greater stability of Q^4 species has the important consequence that upon dissolution a cross-linked network (with as many Q^4 groups as can be formed) is recreated by reaction of silanol groups to yield colloidal silica particles. In phosphates, the most stable bridging bonds (P–O–P bond) are in contrast found in Q^1 species [61]. Cross-linked structures (i.e. Q^3 species) are very susceptible to hydrolysis and rapidly break down in solution at a rate of about $8 \cdot 10^{-3}$ per minute at 25°C , which is about 1000 times higher than for Q^2 [2]. This feature is referred to as the *anti-branching rule* because it results from the lack of resonance stabilization within the three bonds of the PO_4 tetrahedron (Figure 1). The effect is highly apparent in the very rapid decrease of the viscosity of a solution of ultraphosphate caused by hydrolysis. The Q^3 species are in fact so labile that ultraphosphates absorb water even at $300\text{--}500^\circ\text{C}$.

Because they are much more resistant to hydrolysis, Q^2 species are hydrated and dissolved out as complete polyphosphate chains. Longer chains ($n = 10\text{--}50$) give neutral or slightly acidic solutions, shorter chains ($n = 2, 3, 4$) alkaline solutions (e.g. $\text{Na}_5\text{P}_3\text{O}_{10}$ —pH 9.7). For polyphosphates with only weak, low field-strength modifiers, the main factor controlling degradation is the length of the phosphate chain. As such, polyphosphate glasses with weak modifiers are most durable near the metaphosphate composition as their mechanism of dissolution is almost entirely related to chain hydration. In contrast, strong modifiers can have a very significant effect on glass dissolution.

6.2 Chain Stability

After dissolution, polyphosphate chains are relatively stable in neutral/weak alkali solutions at room temperature. The pyrophosphate dimer, for example, could have a half-life in alkaline solution longer than 2000 years. The stability depends on chain length, decreasing from pyrophosphate down to around $n = 10$ as the electron density of the P–O–P linkages drops from 56 in Q^1 groups down toward 24 for Q^2 species. Above $n = 10$, stability begins to increase again. Chain phosphates are stable under alkali conditions at a pH of about 9, but cyclic metaphosphates are so only in neutral solutions as they open to form linear polyphosphates under alkali conditions.

Although polyphosphates are stable in neutral/alkali conditions at room temperature, they rapidly break down at higher temperatures or under acidic conditions. The degradation rate approximately doubles every 5°C to

increase by a factor of $10^5\text{--}10^6$ from 0 to 100°C and it decreases by a factor of $10^3\text{--}10^4$ from strongly acidic to strongly basic conditions. Mechanical strain can increase hydrolysis rates exponentially. At the roots of these differences is the fact that neutral and alkali conditions cause end-chain scission and cycle formation, i.e. orthophosphate and cyclic trimetaphosphate, whereas random chain scission takes place at pH lower than 4. This is the reason why a highly durable iron phosphate glass with a degradation rate of about $4 \cdot 10^{-8} \text{ kg/m}^2/\text{s}$ at pH 7 can dissolve overnight in a HCl solution.

The durability of phosphate glasses is much enhanced by the incorporation of high field-strength modifiers. These form strong P–O–M linkages either by replacing low field-strength modifiers and linking adjacent phosphate chains, or by breaking down P–O–P linkages, thereby replacing Q^2 with more hydrolysis-resistant Q^1 species. These linkages are partly covalent so that the modifier cations become difficult to displace by selective leaching since oxygen is difficult to protonate with a pK_a lower than 2. As a result, the dissolution mechanism becomes rate-limited by the breaking of these strong P–O–M linkages rather than by chain hydration. Hence, the most durable phosphate glasses are those consisting of very short chains bearing hydrolysis-resistant Q^1 dimers and connected with high field-strength modifiers. A combination of different modifiers can then provide an extremely large range of degradation rates (Table 3).

There are of course similarities between phosphate glasses and polyphosphates in solution. Except for lithium, alkali metal phosphates are highly soluble in water (e.g. $\text{NaH}_2\text{PO}_4 \sim 60 \text{ g}/100 \text{ g}$ at 25°C), whereas almost all other metal cations react to form insoluble precipitates. With polyphosphates, the ability to form complexes means that most metals can be held in solution up to a relatively high limit. This sequestering ability allows phosphate glasses to contain large amounts of modifiers without clustering or crystallization, which is very important in commercial applications of polyphosphates.

6.3 Controlled Ion Release

Many applications of phosphate glasses rely on the ability to take up a large quantity of modifier ions or, alternatively, to release continuously into solution either modifiers or polyphosphate anions. Since degradation can be varied to a large range and is (almost) congruent, control of the rate of ion release is possible.

Probably the best known anion application is Calgon®, a water softener developed in the late 1930s by Hall Laboratories. This was a phosphate glass with a $\text{Na}_2\text{O} : \text{P}_2\text{O}_5$ ratio slightly higher than 1.1 : 1 and a polymerization degree n ranging from 15 to 20. Because it contained only sodium, the glass dissolved very quickly to

Table 3 Degradation rates of phosphate glasses containing different modifiers, measured in deionized water at 37 °C with a surface area to volume ratio $\sim 1.2^\circ\text{--}1.6^\circ \times 10^{-2} \text{ m}^2 \text{ l}^{-1}$.

Glass composition (mol %)	Degradation rate ($\text{kg}^\circ \text{m}^{-2} \text{s}^{-1}$)

release anionic chains of polyphosphate in solution. It exchanged with calcium in the water since polyphosphate chains complex much better alkaline earths than alkalis. This ability to sequester ions was monumentally important to the detergent industry and a driving factor in enabling home washing machines and dishwashers. A knock-on effect was an improvement in sewage systems because small quantities of polyphosphate in the water removed the need for grease traps whereas even ppm contents could prevent calcium carbonate (lime-scale) from building up in pipework and boiler systems. Although polyphosphates remain largely unrivalled by organic equivalents, the environmental impact of phosphates and their implication in eutrophication and algal blooms has caused them to be banned in detergents in 1992 in the United States, 2014 in Australia, and 2017 in the EU. Calgon is thus now made of polycarboxylates.

Though detergents have been banned, phosphates are of course widely used in fertilizers. The process of fused calcium magnesium phosphate (FCMP) was developed in 1943 [62], creating a vitreous product by fusion of phosphate rock with magnesium silicate (Mg₂SiO₄, olivine). Although the use of ammonium phosphates and superphosphates dominates the sector, a significant amount of FCMP is used. A glass allows for a slow but continuous release of nutrients, instead of immediately soluble phosphate salts, as a way to reduce phosphate run off and water contamination. In a recent patent, phosphate glass textiles are to be used as root ball nets to provide a static source of fertilizer for young plants.

Perhaps cation-releasing applications of phosphate glasses have been most successful in animal

feeding. The company Bimeda commercializes as COSECURE® pellets of glass fed to cattle. This new kind of *bolus* remains in the stomachs of the ruminants to provide a continuous source of essential trace elements (cobalt, selenium, copper). More recently, other slow-release glasses have been produced for antimicrobial purposes. The product Arglaes® has, for example, been formulated by the company Vitri-Tech to release continuously silver ions, which are effective at killing bacteria.

6.4 Applications to Biology and Food Industry

Phosphates and polyphosphates have a very strong presence in the medical and food industries. This is perhaps not surprising given their importance in biology, in the fabric of DNA and the energy cycle of adenosine triphosphate (ATP). Polyphosphates display antiseptic, cytoprotective, and antiviral activities and have a profound effect on blood clotting. Polyphosphates also interact strongly with proteins, cf. the albumen used as a chemical identifier test for polyphosphate. This interaction is also key to the *coascervation* (separation) of gelatin when tanning leather.

In food, polyphosphates (listed as ingredient E452) perform a variety of tasks. They are among the best-known buffering agents thus used as acidity regulators, thanks to their three acid groups whose *pK* values are widely spaced at 2.1, 7.1, and 12.3. They are good emulsifiers, for example, enabling American cheese to melt without separating. They sequester Ca and Mg, which are required by bacteria, and so prolong the lifetime of food and avoid instances of *Escherichia coli* infection. They can absorb many times their equivalent of water and so provide water retention. They have also been used for their abrasive qualities, for example, in chewing gum and toothpaste.

A neat example of the effects of polyphosphate is instant pudding thickening. It relies on the hydration of sodium pyrophosphate (Na₄P₂O₇), also referred to as tetrasodium polyphosphate, with up to 10 molecules of water. Not only is the pyrophosphate extremely stable at room temperature, but when milk is added, it exchanges Na for Ca to form a stiff crossed-linked gel. Phosphate glasses are also used as leavening agents in baking. From the 1850s, monocalcium phosphate monohydrate (CaH₂PO₄·H₂O) has been used to react with sodium bicarbonate (NaHCO₃) to produce carbon dioxide and obtain the light texture of a foam. But it was not possible to store pre-prepared dough because the reaction is immediate. The solution has been to create a thin glass coating on the surface of the calcium phosphate, which degrades only as the dough is baked at elevated temperatures.

7 Other Applications

7.1 Ion Incorporation

One of the early applications of ion incorporation by phosphate glasses was the *bead test* of mineral analysis. The *microcosmic* salt was heated to form sodium metaphosphate glass, which was used as a “universal solvent” to dissolve mineral samples. The melt was formed on a platinum loop; any trace elements present gave different colors, depending on whether they were in an oxidized or a reduced state. A more recent application of ion incorporation is in the containment of high-level nuclear waste in glass, for which borosilicate matrices are currently predominant (Chapter 9.12). The benefits of phosphates in this application are low melting temperatures to minimize volatilization of radioactive species, low viscosity to improve mixing and homogeneity, and high ability to sequester different radioactive species without phase separation. Low leaching rates, melting temperatures, and crystallization tendencies can be obtained through addition of elements like aluminum and iron, which is why some aluminophosphates are used in Russia [63].

7.2 Seals

The coefficient of thermal expansion of phosphate glasses can be much higher than the high values of $10 \times 10^{-6} \text{ K}^{-1}$ found for lead borate or borosilicate glasses, but are comparable with those of copper, brass, and even aluminum. High-temperature sealing applications have thus been devised to take advantage of these high CTEs in seals operating up to $\sim 500^\circ\text{C}$ or even higher through addition of fillers or partial crystallization. Patents on phosphate sealing glasses (also referred to as solder glasses) have been filed since the 1960s. Compositions make use of the unusual modifier properties of zinc and tin to provide low-viscosity melts that can flow and wet well when melted. These products available from Schott or Corning provide a less toxic alternative to lead-containing borate-based glasses. But a high expansion coefficient is usually at the expense of degradation resistance as strong modifier bonds constrain structural expansion.

7.3 Lubrication

Phosphate ester anti-wear additives have been used in oils for more than 80 years, with the introduction of zinc dialkylthiophosphates (ZDDPs) in the early 1940s [64]. The ZDDP reacts with metal surfaces to create a 50–150 nm wear-resistant iron/zinc phosphate glass layer. Interestingly, the bulk and elastic modulus properties of this layer increase with pressure, which helps the film to maintain its integrity under extreme loads.

However, increasing environmental concerns over phosphates and stricter limits on their use threatens the continued use of these additives.

7.4 Capacitors

Phosphate glasses have interesting electrical properties as well. Barium sodium niobium tungsten phosphate (BaNaNbWP) glasses have demonstrated potential as capacitors through high permittivity values $\epsilon \sim 160\text{--}580$ (cf. silica ~ 4) [65] and high electrical breakdown resistance. Additionally, some silver phosphates have shown promise as solid-state electrolytes, with reported ion conductivities as high as $2 \times 10^{-2} \text{ S/cm}$ at 25°C [66]. By control of oxidation states, semiconductors can be produced using Fe and V glasses.

7.5 Miscellaneous

Polyphosphoric acid glasses have little practical purpose, save for the use of superphosphoric acid with a melting point of 16°C because it allows for easy transport of phosphoric acid for use in high-strength fertilizers.

Phosphate glasses have been used as hydrofluoric acid-resistant labware since 1884 (US 295,410), as phosphate does not form a volatile fluoride like silicates. However, the development of plastic labware has made these applications less valuable.

In metrology, phosphate glass standards might be useful. For viscosity, the borosilicates produced in the mid-90s have now limited stocks and are poor calibrants for phosphate glasses owing to the decades difference in viscosity. Borosilicates may in addition suffer from instability upon extended melting through boron volatilization [40]. The low vapor pressure of borophosphates and a HF-free cleaning process would thus make these glasses good standard materials although their potentially corrosive action on expensive platinumware should be taken into account.

8 Perspectives

Phosphate glasses have benefited from an increasing research over the last two decades to take advantage of their unique characteristics. In addition to the use of modifiers to improve their durability by the introduction of strong P–O–M linkages, recent studies have considered surface modification techniques such as ion exchange (Chapters 3.12 and 6.7). Additionally, treatments with nitrogen compounds to nitride the glass surface have been effective in reducing degradation rates as well [67].

Growing concerns about phosphates in food and the environment may inhibit developments in those areas, or may rather be a boon in establishing glassy polyphosphates as a means of controlling rates of release and reducing excess phosphate. Improved understanding of phosphate biology and development of enhanced biological phosphorus removal (EBPR) techniques could provide a means of effective control of eutrophication [7].

While laser applications are making more use of crystalline materials, phosphors are crucial components in solid-state and thin-film lighting (Chapters 6.9 and 6.10) at a time where enhanced concern for energy saving make efficient lighting more in demand. Current LEDs are encapsulated by organic polymers or silicones, which are limited by heat, UV exposure, and gas permeability. Phosphate glass versions can withstand higher temperatures, are not degraded by UV, and are almost completely gas impermeable. There may also be potential in information storage. Ion and proton transport is also likely to play a significant role in the coming years, contributing to solid-state electronics, batteries, and fuel cells. Other opportunities lie in the use of phosphate glass as lead-free alternatives, for instance, in zero photoelastic constant applications in electric field sensors. There is also significant activity around mass-produced aspherical optics and applications such as IR filter systems in digital photography.

Phosphate glasses in medicine are receiving increasing interest [68] with fibers, composites, and microspheres that are beginning to find applications [69]. High calcium and phosphate contents lend themselves to use in hard tissues and polyphosphates have hemostatic properties. Their optical properties also have potential in phototherapies. Finally, new manufacturing techniques, such as microwave heating [70] and more recent activities looking at blending of glasses, may make for less aggressive melts and realize more use of phosphate glass waste containment.

Bulk Metallic Glasses

Dmitri V. Louzguine-Luzgin¹ and Akihisa Inoue²¹ WPI Advanced Institute for Materials Research and AIST-Tohoku Mathematics for Advanced Materials – Open Innovation Laboratory, National Institute of Advanced Industrial Science and Technology, Tohoku University, Sendai, Japan² International Institute of Green materials, Josai International University, Togane, Japan

1 Introduction

In principle, any liquid can vitrify upon cooling provided that the cooling rate is high enough (Chapter 3.1). However, *high enough* can mean rates as high as 10^8 – 10^{10} K/s required for pure metals like V, Fe, or Co, with the consequence that the amorphous materials that can be obtained and stabilized versus crystallization even at room temperature are only nanometric spheres [1]. For obvious structural reasons (Chapter 3.1), pure metals are actually among the worst glass formers.

Hence, it was a real breakthrough when Pol Duwez (1907–1984) and his collaborators in 1960 vitrified an Au–Si liquid at a rate of about 10^6 K/s in the form of splat-cooled flakes [2]. This first Au–Si glass was a chance discovery because the actual goal of the experiments was to quench in the form of crystalline solid solutions binary metal liquids that separated into two different crystals even upon relatively rapid cooling. Understanding at once the importance of the new glass family, Duwez and his team members then showed that vitrification could be achieved in other metallic systems, such as Fe–P–C [3], especially when a metalloid was added to Fe in a 25 : 75 or 20 : 80 ratio. From a physical standpoint, in these metallic glasses they observed ferromagnetism, relatively high electrical resistivity, superconductivity, and other properties existing in crystals while noting otherwise some unusually high resistance to chemical attacks by acid and other corrosive solutions.

These unexpected findings raised fundamental issues, at the same time they paved the way to valuable applications. High mechanical properties resulted from the lack of dislocations and grain boundaries existing in crystalline metals, whereas the extremely low hysteresis losses of ferromagnetic glasses would later be used to reduce energy losses in the electrical transformers. Significant efforts had to be done, however, to improve the glass-forming ability (GFA). The solution was to optimize the chemical composition of the starting melts so as to produce real bulk glasses as three-dimensional objects with the size of at least 1 mm in every spatial dimension needed for practical applications.

Many different alloys have been investigated so far for this purpose, based on rare-earths, Mg, Zr, Ti, Fe, Co, Pd, Pt, Au, Ag, Cu, Ni, or Ca. The outcome of this extensive work has been the production of many different metallic glasses of 1–100 mm characteristic size [4, 5] with methods that include fluxing for a Pd–Ni–P glass of centimeter scale was then produced in the 1980s by fluxing [6]. Besides, hard and soft ferromagnetic alloys based on Nd and Fe or Co, respectively, were also produced and studied [7]. Since then these *bulk* glasses (Table 1) have found their ways in a wide range of products such as sports goods, watches, electromagnetic-wave shields, optical devices, power inductors, mini transformers, micro-gear motor parts, pressure sensors, Coriolis flow meters, coating materials, or medical instruments. From a practical standpoint, an additional advantage has been the possibility to cast metallic glasses with available processes, which include the economically efficient *net-shape casting* technique, thanks to which accurate dimensions and high surface quality are achieved without subsequent machining.

Reviewers: J. Antonowicz, Laboratory of Metallic Glasses, Warsaw University of Technology, Warszawa, Poland
M. Stoica, Leibniz Institute for Solid State and Materials Research, Dresden, Germany

Table 1 Representative metallic glasses: alloy systems and important mechanical and other properties, including typical (D_t) and maximum (D_m) critical ingot diameters.

Alloy system	D_t, D_m (mm)	T_g (K)	Yield strength (GPa)	E (GPa)	HV
Zr–Cu–TM–Al	~10, 20	650–750	~1.7	80–90	480–550
Pd–Cu–Ni–P	~20, 80	550–600	~1.5	80–95	480–520
Ti–Cu–Sn–TM	~3, 7	600–700	~2	95–105	~650
Mg–Cu–RE	~10, 25	400–450	0.7–0.9	45–55	280–310
Ca–Mg–Al–TM	~5, 10	400–500	~0.35	20–35	~150
La–Cu–Al	~5, 20	400–450	0.6–0.9	30–45	200–250
Fe–Co–TM–ME	~5, 15	800–950	~4	~200	900–1000

RE, rare-earth metal(s); ME, metalloid(s); TM, other transition metal(s).

To review these various features, the present chapter will first discuss the glass formation mechanism. Next, the structure of metallic glasses will be discussed. Mechanical properties and the formation of shear bands upon stress will then be presented before the deformation mechanisms are discussed in more detail, particular attention being paid to the plasticizing function of nano/microscale crystalline phases that can precipitate within the overall amorphous matrix. Soft and hard magnetic properties and applications will be finally reviewed along with structural, chemical, and other specific uses of metallic glasses. This chapter is by no means comprehensive owing to the impressive size now reached by the literature on metallic glasses. Interested readers are thus referred to available monographs for more detailed accounts [8, 9].

2 Glass Formation

2.1 Vitrification Criteria

Metallic glasses deserve their names because they display upon cooling or subsequent heating the conspicuous features of a glass transition, namely, abrupt increases in the specific heat capacity (C_p) and thermal expansion coefficient (α) in relatively narrow temperature intervals. On heating the glass above the glass-transition temperature T_g , the supercooled liquid forms and generally begins to crystallize at a temperature T_x well before the stable liquid domain is reached at the liquidus temperature T_l (Figure 1). Upon heating at rates on the order of 10^1 K/min, the T_g values observed in these measurements are close to the temperatures at which the viscosities of the supercooled liquid are about 10^{11} – 10^{12} Pa·s.

In spite of their chemical diversity, bulk metallic glasses share three other features [4]: (i) they, in general, belong to multicomponent systems that ensure large enough

Figure 1 A typical DSC thermogram of a metallic glass crystallizing through metastable stages: glass-transition temperature (T_g), onset temperature of crystallization (T_x), several exothermic peaks, endothermic melting peak on heating and exothermic peak on cooling and approximate liquidus (T_l^*), and solidus (T_s^*) temperatures. The heating and cooling rates were different.

configurational entropies and, therefore, freezing-point depressions as deep as possible (Chapter 5.2) and viscosity increases as fast as possible on cooling; (ii) their constituent elements have significant atomic size ratios exceeding 1.12 so as to ensure high packing density between “solvent” and “solute” atoms; (iii) and enthalpies of mixing in the systems are largely negative.

These criteria need to be satisfied to achieve not only a good GFA but also a relatively high thermal stability against crystallization. Complex chemical compositions not only allow relatively high viscosities but also make crystallization more difficult by increasing the number of potentially precipitating crystal line phase. In an anthropomorphic way, the effect is expressed by the *principle of confusion*: upon continuous cooling, the liquid finds itself frozen into a glass before having had enough time to choose which of these crystals competing for nucleation and growth would actually form. As an

example, the good GFA of the Fe–Cr–Mo–C–B–rare earth liquids has been assigned to the low growth rate of the χ -Fe₃₆Cr₁₂Mo₁₀ phase along with the destabilization of competing crystalline phases that would form by eutectic crystallization [10].

Without being of universal validity, the following three parameters are useful to characterize more precisely glass formation. They can be determined most conveniently from differential scanning calorimetry thermograms (Figure 1). The first two are the reduced glass-transition temperature, $T_{rg} = T_g/T_l$, and width of the supercooled liquid region, $\Delta T_x = T_x - T_g$. Bulk metallic glasses are then obtained in a narrow 0.5–0.65 range of T_{rg} values whereas ΔT_x vary much more with composition from about 15 to 120 K. These two parameters have been combined into the third, $\gamma = T_x/(T_g + T_l)$, which appears to discriminate better the alloys with good GFA by values ranging from about 0.35 to 0.45 [11]. Many similar parameters were further developed later [12]. Also, in metallic as in other kinds of systems, liquids with high fragility (high parameter m) are generally not good glass formers because, for a same reduced T_{rg} , they have lower viscosities between T_g and T_l and, therefore, higher crystal nucleation and growth rates with the exception of relatively fragile Pd–(Ni, Cu)–P glasses that have extremely large T_{rg} values [13].

2.2 Glass Transition

The glass-transition temperature is usually measured by calorimetry on heating. For iron-based glasses, T_g is as high as ~900 K but it is close to room temperature for Ce- and Ca–Li-based glasses and as low as 308 K for Ca₆₅Li_{14.54}Mg_{12.46}Zn₈ [14].

As usual (Chapter 3.6), the specific heat capacity C_p of a metallic glass near the room temperature follows the Dulong and Petit law of 3R per mol and is slightly higher than that of the crystalline counterpart (Figure 2). In general, the C_p increase on heating in the glass-transition region is as abrupt as in other glass-forming systems. For some Zr- and Au-based alloys, some unusual features can nonetheless be observed in step-scan measurements when relaxation sets in [15]. These particular features are two successive sigmoidal-type C_p increases upon heating that cause the C_p difference between the supercooled liquid and the crystal to reach about 60%. With only a slight hysteresis, these variations are largely reversible upon cooling (Figure 2). Such a two-step glass transition at around 340 and 380 K is likely related to differences in the temperature dependences of diffusion coefficients within the glass. At lower temperatures, diffusion by atomic hopping would be several orders of magnitude faster than by cooperative shearing so that it is the only process involved at the onset of atomic mobility at

Figure 2 Two-step glass transition of Au₄₉Cu_{26.9}Ag_{5.5}Pd_{2.3}Si_{16.3} in heat-capacity measurements made at 5 K/min upon both heating and cooling. Data for the crystalline state are included for comparison. Source: Reproduced from [15] with permission of Elsevier.

the first transition. With increasing temperature, however, the kinetics of cooperative shearing eventually catches up to cause the second transition. Hence, an interesting consequence of the process is that the mobility of different elements of the alloy freezes in at different temperatures starting from larger atoms with lower diffusivity.

On heating up to T_g , the glassy structure relaxes, making the samples more dense and brittle. However, one can achieve an opposite process of structural rejuvenation by heating the glass above T_g and then fast cooling [16]. Structural rejuvenation is also achieved by cryogenic cycling [17].

2.3 Vitriification Versus Crystallization

As usual, the vitrifiability or GFA of alloys is determined by intrinsic and extrinsic factors (Chapter 5.4), being, for example, limited by homogeneous or heterogeneous crystal nucleation [18], respectively, and by modification of the cooling rate. Extrinsic factors are related to inclusions or dissolved impurities in the melt, poor finish, or cleanliness of the mold surface that reduce the cooling rate, turbulent flow during solidification, etc. [19]. The GFA of some metallic glasses is promoted by the use of oxide fluxes. Such an efficient flux is molten B₂O₃ for Pd-based glasses and other systems in which the size of amorphous samples is increased, thanks to suppressed heterogeneous nucleation [6]. The point is also well illustrated by Al-based glasses for which the use of an MgCl₂–CaCl₂ flux allows their critical casting thickness to be increased from about 1 mm to a record value of 2.5 mm for the Al₈₆Ni_{6.75}Co_{2.25}Y_{3.25}La_{1.75} composition [20].

Heterogeneous nucleation is by definition peculiar to the process involved. Hence, homogeneous nucleation deserves more attention in view of its general nature. For metallic glasses, however, the boundary between homogeneous and heterogeneous nucleation can be somewhat blurred because one cannot always avoid upon glass formation the formation of a quasicrystal nuclei or even of crystal – an example of growth-rate-controlled glass is given in [10]. In these cases, crystals can grow readily upon heating as revealed by the exothermic signals present in thermograms.

In a general way, four kinds of processes are distinguished for crystallization. In the simplest, the precipitates are either isochemical with the starting metallic glass (polymorphic reaction) or not (primary crystallization). During eutectic crystallization, two or more phases nucleate and grow conjointly (Chapter 5.2). In the fourth case of spinodal/binodal decomposition (Chapter 5.2), the crystallization process is preceded by liquid–liquid (or glass–glass) phase separation. In all cases crystallization is a spontaneous process, which lowers the Gibbs free energy (G) of the system. According to the classical nucleation theory (Chapter 5.4), the growth of a nucleus of radius r is first opposed by the creation of interface energy (along with elastic-deformation energy), until the radius exceeds a critical value r_c from which the negative volumetric ΔG caused by the crystallizing fraction predominates. The nucleation and growth rates have different temperature dependences. The number of critical-size nuclei per unit volume is proportional to $e^{-\Delta G_c/RT}$, where ΔG_c is the Gibbs free energy of formation of a critical nucleus, which depends on the extent of supercooling. On the other hand, the frequency of atomic transfer through the interface is proportional to $e^{-Q_N/RT}$. Hence, the nucleation rate I is:

$$I = I_0 \cdot e^{-Q_N/RT} \cdot e^{-\Delta G_c/RT}, \quad (1)$$

where $Q_N \sim 1/\Delta G^2$ is the activation energy for transfer of the atoms across the surface of a nucleus. The growth rate (u) is proportional to the frequencies of the transition from liquid/glass ν_{l-s} to solid and back, ν_{s-l} with

$$\nu_{l-s} = \nu_0 \cdot \exp.(-\Delta G/RT). \quad (2)$$

For interface-controlled growth with the activation energy Q_g , the rate thus is:

$$u = u_0 e^{-Q_g/RT} \cdot (1 - e^{-\Delta G/RT}), \quad (3)$$

If I and u are time independent and the reaction is interface-controlled, the kinetics of the nucleation and growth of spherical crystals can be analyzed in terms of the Kolmogorov–Johnson–Mehl–Avrami theory (Chapter 5.4). The general exponential equation for the fraction transformed x then is:

$$x(t) = 1 - \exp((-\pi/3)Iu^3t^n), \quad (4)$$

where n is the Avrami exponent. The time–temperature-transformation diagrams created in the isothermal mode or under continuous heating are useful for comparing the thermal stabilities of different glasses [9].

One finds that reduced supercooling (undercooling) before crystallization from the melt is the smallest for easily nucleating quasicrystals, larger for crystal approximants and the largest for crystalline phases [21].

2.4 Density and Entropy

The density of a liquid increases faster with temperature than that of its crystalline counterpart. By analogy with the well-known Kauzmann's entropy crisis [8], a supercooled liquid would thus become the densest phase at some temperature if the glass transition was not taking place. For liquid Ni and Fe, quantum mechanics [22] as well as classical [23] molecular dynamics simulations have indeed predicted vitrification at temperatures slightly higher than that of such a density crisis. One should remember that FCC structure of Ni and γ -Fe (as well as HCP) is the densest possible packing of singular-type atoms.

2.5 Viscosity

The viscosity of a supercooled liquid changes drastically with temperature, especially close to T_g . Although the transition takes place in a temperature interval, an arbitrary glass-transition point is defined as a temperature at which the viscosity of a liquid reaches 10^{12} Pa·s on cooling. For some materials this value belongs to the glass-transition region defined by C_p measurement, but it is not the case for others [24].

Recent studies have emphasized the importance of the electronic structure. For example, stronger covalent bonding between metal atoms and phosphorus has been observed in Pd–Cu–Ni–P melts cooled down close to the glass transition. In turn, this stronger bonding causes structural changes in the liquid alloy that result in a more fragile character of the temperature dependence of its viscosity [25].

2.6 Thermal and Electrical Conductivity

Thermal conductivity is a fundamental property in glass formation since it controls the rate at which a liquid is cooled and, therefore, the critical casting thickness. A disordered structure generally impedes to some extent thermal conduction (Chapter 4.5). The thermal diffusivity/conductivity of amorphous alloys conform to this rule

Table 2 Room-temperature electrical conductivity, thermal diffusivity, and thermal conductivity of bulk metallic glasses [9].

Alloy	Thermal diffusivity (mm ² /s)	Thermal conductivity (W/m·K)	Electrical conductivity (μΩ·m) ⁻¹
Pd ₄₀ Ni ₁₀ Cu ₃₀ P ₂₀	1.62	5.11	0.541
Zr ₅₅ Al ₁₀ Ni ₅ Cu ₃₀	2.2	5.02	0.53

since they are slightly smaller than those of their crystalline counterparts and they slightly increase with temperature. As also expected, the typical room-temperature values listed in Table 2 are several times higher than for oxide glasses (Chapter 4.5), consistent with the differences between metallic and mixed ionic/covalent bonding between these phases [19].

Likewise, the electrical conductivity of metals is lower in the amorphous than in the crystalline state. Typical values of the electrical resistivity are 1–3 μΩm (Table 2). Some metallic glasses do exhibit moderate decreases of the electrical conductivity with temperature, but less simple variations are observed in alloys such as Pd₄₀Ni_{40-x}Cu_xP₂₀ for which the temperature dependence changes from positive to negative when the Cu content exceeds 15 % [26]. A similar change takes place in the Pd–Ni–P system when the P content becomes more than 24 %.

3 Structure

3.1 Short-range Order

As determined by diffractometry (Chapter 2.2) or computer simulations (Chapter 2.8), the structure of metallic glasses differs in many respects from that of network-building oxides (Chapter 2.5). The small density differences between metallic glasses and their crystalline counterparts have made clear that the former phases consist of efficiently packed clusters rather than of dense random packing of atoms. Atomic clusters about 1 nm size have been directly observed by scanning tunneling microscopy [27] whereas medium-range order zones and even nanocrystals are present in some glassy alloys.

Atomic short-range ordering is also seen in molecular-dynamics simulations of Fe (Figure 3). In an amorphous Cu–Ti–Zr alloy (Figure 4), the first peaks are assigned to well-defined interatomic interactions whereas some order persists up to about 1–2 nm [28].

Interesting correlations between such structural changes and non-Arrhenian rheology have been made

**Figure 3** Room-temperature cell of glassy Fe produced by a molecular-dynamics simulation of a set of 128 000 atoms.**Figure 4** Pair-distribution function of a Cu–Zr–Ti alloy determined from synchrotron X-ray diffraction experiments [28] and fitting of its first maximum with 6 Gaussian peaks (inset). Reproduced with permission of Elsevier.

for a Pd–Cu–Ni–P melt where both Ni and Cu form strong covalent bond with P through p-d hybridization whereas Pd–Cu–Ni interactions are metallic. When plotted against temperature, the ratio between the areas of the (Cu, Ni)–P versus Pd–(Ni–Cu) and Pd–Pd peaks of the pair-distribution function (PDF) changes on cooling down to the glass transition below which it remains constant (Figure 5) [25]. In other words, the proportion of (Ni, Cu)–P clusters remains constantly low in the glass range. Then it increases in the liquid phase on heating,

Figure 5 The first two Gaussian peaks at 298 K of the pair-distribution function of a Pd–Cu–Ni–P glass and the rapid decrease of their area ratio above the glass transition temperature. Alloy vitrified under vacuum and studied by X-ray diffraction at a synchrotron facility in-situ on cooling. *Source:* Data from [25] with permission of the American Institute of Physics.

causing the rheology to be non-Arrhenian because this disruption of short-range order results in a decrease of the activation energy for viscous flow.

3.2 Structural Heterogeneities

Most metallic glasses have a uniform structure at a scale larger than about 1–2 nm (Figure 6) as shown by transmission electron microscopy (TEM) and high-resolution TEM (HRTEM) (Chapter 2.3) [28]. However, atomic clusters and phase separation in some alloys lead to the locally inhomogeneous structure found in Pd-based glass, for example [29]. Surface heterogeneities may also exist [30], like those observed on the $\text{Au}_{49}\text{Cu}_{26.9}\text{Ag}_{5.5}\text{Pd}_{2.3}\text{Si}_{16.3}$ glassy rods that have a thin crystalline surface layer, consisting of grains of an Au-based solid solution embedded in the amorphous phase. Whereas this solution gives a nice yellow color to the sample surface, the internal part of the ingot is metallic gray owing a relatively high Si content [9].

3.3 Phase-separated Glasses

Another important feature is the solid- or liquid-state immiscibility (Chapter 5.2) that prevails in some metallic systems. Solid-state immiscibility between Zr and Nd causes a phase separation in the Zr–Nd–Al–Ni system. A globular phase in the $\text{Zr}_{30}\text{Nd}_{30}\text{Al}_{15}\text{Ni}_{25}$ alloy is Nd-rich whereas the surrounding matrix phase is Zr-rich (Figure 7) [31]. The elongated Zr-rich phase with the nominal $\text{Zr}_{53.0}\text{Nd}_{9.2}\text{Al}_{13.9}\text{Ni}_{23.9}$ atomic composition produces a larger halo ring in a SAED pattern, whereas the second glassy phase is Nd-rich with the $\text{Zr}_{17.8}\text{Nd}_{43.4}\text{Al}_{16.1}\text{Ni}_{22.3}$ composition.

3.4 Porous Glasses

Open- [32] and closed-pore [33] type glassy alloys are produced in metallic systems. Owing to their low density, these metallic glasses with open or closed porosities are very promising materials for structural applications. Their porosity is created by the precipitation of a hydrogen gas initially dissolved at some high pressure into the liquid $\text{Pd}_{42.5}\text{Cu}_{30}\text{Ni}_{7.5}\text{P}_{20}$ alloy [33]. The pore size and distribution are then controlled by the pressure drop during foaming and cooling. The hydrogen dissolved is released as bubbles, which are small and evenly dispersed if foaming takes place at about 10% of the dissolution pressure (Figure 8). For larger pressure drops, larger pores and, thus, higher porosities are obtained. A similar result with a porosity of up to 10% is achieved if the porous glass is reheated in the supercooled liquid region to let the bubbles expand. Anticipating the following section, we note at once that the mechanical properties of porous samples can be improved as indicated by the strain–stress curves of the aforementioned Pd–Cu–Ni–P glass (Figure 9). With an existing porosity, the yield strength is only slightly reduced whereas the compressive plasticity of the porous sample is much higher (Figure 9). A 5.7% porous sample has, for instance, a $\sigma_{0.2}$ value of 1420 MPa, a Young's modulus of 88 GPa, and a plasticity of about 19%. The ductility of the glass is greatly improved by a control of the pore size and volume fraction.

3.5 Nanostructured Materials Produced by Thermal Crystallization of Metallic Glassy Phase

At large supercooling, a nanostructure can develop in an overall amorphous matrix if the rate of crystal nucleation is rather high while the rate of crystal growth is low. The phenomenon is common upon primary crystallization of

Figure 9 Comparison between the compressive stress–strain curves of porous (5.7% porosity) and pore-free Pd–Cu–Ni–P glassy sample ($P = 0\%$).

glasses with a long-range diffusion-controlled growth. Nanocrystals can then represent barriers for the deformation of the glassy matrix but their efficiency to block the shear deformation, of course, depends on their size and volume fraction [8].

Quasicrystals are quasiperiodic in one, two, or three dimensions but their diffraction symmetries are forbidden in real crystals because they lack 3-D translational periodicity. In various metallic glasses, one observes on heating the formation of *icosahedral* quasicrystals described by a six-dimensional space group, which characterizes the symmetries of the icosahedron (the regular 20-face polyhedron). These icosahedral quasicrystals, for instance, form upon annealing of $\text{Hf}_{65}\text{Pd}_{17.5}\text{Ni}_{10}\text{Al}_{7.5}$ glass where they show diffuse boundaries with the glass matrix (Figure 10) [30].

These quasicrystals are also found in Zr–Al–Ni–Cu–Ag, Zr–Al–Ni–Cu–Pd, and various other systems as a Cu-based icosahedral phase is observed after heat treatment in Cu–Zr–Ti–NM alloys (NM denotes noble metals) containing Pd and Au [9].

4 Mechanical Properties

4.1 High vs. Low Temperature

On heating up to slightly above T_g , metallic glasses first exhibit a non-Newtonian flow before becoming Newtonian in the supercooled liquid region. As usual, the boundaries between three ranges of inhomogeneous deformation, non-Newtonian flow, and finally Newtonian flow shift toward lower temperatures when the

Figure 10 Electron microscopy micrographs of icosahedral quasicrystals in the $\text{Hf}_{65}\text{Pd}_{17.5}\text{Ni}_{10}\text{Al}_{7.5}$ glass annealed for 600 s at 873 K. Source: Reproduced from [30] with permission of the American Institute of Physics.

loading rate decreases because the timescale of the experiment then becomes shorter compared to the intrinsic structural relaxation times of the material. Little needs to be said about Newtonian flow, which involves only quick structural rearrangements in the liquid. Attention will thus rather be paid to the mechanical responses of metallic glasses below the glass transition temperature and to the modes of deformation of the materials, which can be complex.

4.2 Quasi-static Room-temperature Properties

Not surprisingly, metallic glasses have the excellent mechanical strength. Owing to their dense atomic packing, their elastic constants do not differ much from those of their crystalline counterparts. A high hardness is combined with good wear resistance and large elastic deformation with strengths of about 2 GPa for Cu-, Ti-, and Zr-based glasses as well as of about 3, 4, and 5 GPa for Ni-, Fe-, and Co-based glasses, respectively. For example, Co–Fe–Ta–B glass has a ultrahigh fracture strength exceeding 5 GPa whereas the tensile strength of Co–Ta–B glasses approaches 6 GPa. Most of these glasses are brittle since, with a small number of exceptions [34], they are not ductile in tension. Hence, many of them fail when the elastic deformation limit is exceeded although some can be deformed plastically upon room-temperature compression.

A noteworthy phenomenon is that some extremely strong glasses in the as-cast state become brittle when annealed close to the glass transition or even after a long period of time at room temperature. For $\text{Zr}_{50.7}\text{Cu}_{28}\text{Ni}_9\text{Al}_{12.3}$ glass, however, this *embrittlement annealing* has been opposed by the deposition of a crystalline W coating, which preserves the excess volume of the material and enhances both its strength and plasticity [35]. A more general way to arrive at the same result is to rejuvenate the glass structure and restore plasticity through cryogenic thermal cycling [17]. Cyclic cooling in liquid nitrogen increases the resistance to compression and extension through flexible deformation within nanoscale zones. In a way reminiscent of the thermal tempering of oxide glasses (Chapters 3.12 and 6.7), it results from the production of internal stresses through local differences in thermal expansion in heterogeneities of the atomic structure.

4.3 Fracture Toughness

The fracture toughness, i.e. the ability of a material to resist crack propagation and fracture, is also excellent for some metallic glasses. The invention of $\text{Pd}_{79}\text{Ag}_{3.5}\text{P}_6\text{Si}_{9.5}\text{Ge}_2$ glass with a fracture toughness up to 200 $\text{MPa}\sqrt{\text{m}}$ (though only a small size sample was tested) and a high damage tolerance was particularly instrumental to increase the scientific interest paid to these fascinating materials [36]. For compositions that vitrify readily, the availability of large enough samples has actually allowed accurate mechanical measurements to be performed without yielding the spuriously high values that could otherwise be obtained. Whereas the fracture toughness obtained on 7 mm thick fatigue pre-cracked tension specimen of the $\text{Zr}_{41.2}\text{Ti}_{13.8}\text{Cu}_{12.5}\text{Ni}_{10}\text{Be}_{22.5}$ glass is 55 $\text{MPa}\sqrt{\text{m}}$ [37], heat treatment resulting in partial or full crystallization leads to a 50-fold reduction in K_{Ic} values to 1.21 and 1.04 $\text{MPa}\sqrt{\text{m}}$, respectively. Values of fracture toughness in the range 35–75 $\text{MPa}\sqrt{\text{m}}$ have been found in three-point bending tests for pre-cracked and notched $\text{Zr}_{55}\text{Al}_{10}\text{Ni}_5\text{Cu}_{30}$ specimens [9].

4.4 Friction and Wear Resistance

Metallic glasses have also been investigated with respect to wear and friction under dry sliding conditions. Friction coefficients range from 0.30 to 0.45. The wear resistance of Zr-based glasses is about 5×10^{11} Pa whereas that of Fe-based glasses reaches about 5×10^{14} Pa and could be even higher for Co-based glasses [38]. Owing to their low elastic moduli, high specific strength and excellent processing characteristics in the supercooled liquid state, metallic glasses appear to be promising materials for

applications in micromechanical systems. Their tribology has thus also been studied at the nano and atomic scales.

4.5 Fatigue

The fatigue-endurance limits of some Zr-based glasses are comparable with those of high-strength crystalline alloys (Table 3) [39]. In video-resolved thermographies of mechanical damage in metallic glasses, one can observe thermoelastic and heat-transfer effects. In addition, a thermoelastic degradation attributed to free-volume accumulation is observed at the center of the specimen. But no shear bands (see Section 5.1) are observed before failure during these fatigue experiments. The crack-initiation mechanisms upon fatigue testing could thus be surface-voids and defects, and not the shear band of tensile testing.

4.6 Low-temperature Mechanical Properties

The maximum compressive stress of metallic glasses increases with decreasing testing temperatures [40]. For $\text{Zr}_{64.13}\text{Ni}_{10.12}\text{Cu}_{15.75}\text{Al}_{10}$, the yield stress under compression is, for instance, 1.8 and 2 GPa at room and liquid-nitrogen temperatures, respectively. This is reflected in acoustic-emission experiments in which the acoustic signal is significantly reduced at low temperatures [41], although localized shear bands are still formed (cf. Section 5.2). The transition from serrated to non-serrated plastic flow (see the following section) at liquid-nitrogen temperature thus suggests that the shear-band propagation velocity decreases because of the increased viscosity of the deforming regions.

5 Deformation Behavior at Room Temperature

5.1 Shear Transformation Zones

Although the majority of metallic glasses are brittle even under compression, some of them display a significantly higher compressive plasticity than others. Such an enhanced plasticity can be related to a high Poisson's ratio [42], an in-situ nanocrystallization, or a glass phase separation [9]. Also, it appears that embrittlement of Mg- and La-based alloys is caused by the inclusion of oxide particles of micron-size scale that act as stress concentrators because oxygen is soluble in solid Zr and Ti, but not in solid Mg and La [43].

A metallic glass thus begins to deform when a shear transformation zone forms near a stress concentrator, be it a flaw or a surface notch, which induces structural disordering. In the next step such zones unify in the form of a front that propagates as a shear band. At this stage, the strain within the band and the values of shear offset are rather small, causing small stress drops. A certain band can then gradually reach the opposite surface of the sample, leaving behind it either a relatively flat or a complex-shaped, curved 2-D interface. Between the two parts of the sample a friction-induced vibration manifests itself as a slip-stick process while further deformation takes place in this band as indicated by a change in the stress-strain curve. In other words, formation of new shear bands with relatively small shear offsets first prevails before deformation proceeds mainly through the existing dominant shear band(s) (Figure 11). These two types of deformation regimes may result in the bimodal distribution of the shear offsets observed earlier.

Table 3 Mechanical strength and fatigue data of bulk metallic glasses tested at 10 Hz frequency and the ratio of minimum to maximum stress of 0.1.

BMG	Tensile strength (MPa)	Geometry	Testing scheme	Fatigue limit (MPa)	Fatigue ratio

5.2 Shear Deformation Bands

At lower temperatures metallic glasses flow plastically in an inhomogeneous way through the formation and propagation of shear bands, which are 10–20 nm thick and manifest themselves as surface steps up to several micrometers in height. Because the process is considered to be stochastic, the dominant shear band that eventually forms does so at different strains in different samples. Experimentally, the formation of shear bands is revealed by wavy, or *serrated*, stress–strain curves, every small stress drop being caused by an individual event (the so-called Portevin–Le Chatelier effect). At room temperature, it is because of this dominant mode of plastic deformation that metallic glasses have no tensile ductility, except in the few special cases of thin sections of hypoeutectic alloys tested at relatively high strain rates. Other examples are Zr-based thin foils for which in-situ TEM observations have demonstrated the much higher ductility of hypo- compared with hypereutectic alloys, which originates in their larger excess volumes.

5.3 Shear Softening

Shear softening may result from local heating or be stress driven instead. In a shear band, however, friction in a liquid layer may alternatively act as a heat source. When the central zone of the shear band heats up at high strain rates through friction forces, its viscosity can decrease by several orders of magnitude and, thus, result in an increase of the shear speed. But at some point the band finds itself stopped, likely owing to an axial-stress decrease, until the next round of stress increase. Eventually, fracture suddenly takes place at a critical shear offset because of sudden viscosity reduction caused by the heat released through friction forces.

A change in the deformation stage is observed in metallic glassy samples [44]. In the plastic range, the strain curve of a typical 2 : 1 height to diameter ratio cylindrical $\text{Zr}_{62.5}\text{Cu}_{22.5}\text{Fe}_5\text{Al}_{10}$ sample subjected to continuous loading illustrates a change in deformation mechanisms observed in metallic glasses (Figure 11). From the beginning to the eventual fracture, plastic deformation proceeds discontinuously as indicated by the repeated stress drops observed. After about 2% of plastic deformation, the change observed in the magnitude distribution of the stress drops thus indicates a limit between two deformation regimes. In the first, new shear bands repeatedly form and propagate throughout the sample; the second one begins when they give rise to a major/dominant shear band, which later propagates in a stick–slip way.

Interestingly (Figure 12), cylindrical 1 : 2 samples can deform to large strains without forming such a dominant shear band because this aspect ratio makes it possible to keep a nearly homogeneous deformation at a

Figure 11 The wavy, or *serrated*, stress-deformation relationship of a 2 : 1 (height to diameter ratio) cylinder of the $\text{Zr}_{62.5}\text{Cu}_{22.5}\text{Fe}_5\text{Al}_{10}$ glass upon room-temperature compression. (a) Stress (top curve) and repeated stress drops (bottom, diamonds) causing the plastic deformation shown by the video snapshots from 0 up to 3.5%, at which fracture took place. (b) Frequency distribution of the magnitude of stress drops calculated from the continuous strain–stress curve in (a) in two ranges, namely, from 0 to 2.5% and from 2.5 to about 4%. macroscopic scale [45]. From differential scanning calorimetry (DSC) thermograms of deformed samples (Figure 13), complementary information can be drawn in terms of T_g , T_x , and exothermic peak (T_p) temperatures, and of enthalpies of relaxation (ΔH_r), overshoot (ΔH_o), and crystallization (ΔH_c). The values of T_g and T_x decrease but ΔH_r and ΔH_o increase at 0.24 and 0.68 strain whereas other parameters are less affected.

Before crack initiation takes place at a larger strain, the formation of a great number of shear bands may thus have a twofold effect on the properties of a strongly deformed metallic glass. Locally, a higher energy state is reached (as in case of glassy phase rejuvenation), which is released after failure of the sample. The areas deformed either plastically (within the shear bands) or elastically (at the edges of not well-developed shear bands which did not propagate

Figure 12 Strain–stress curves of a 1:2 (height to diameter ratio) cylinder of the $\text{Zr}_{62.5}\text{Cu}_{22.5}\text{Fe}_5\text{Al}_{10}$ glass upon room-temperature compression. till the other side of the sample) release a significant amount of extra heat upon structural relaxation whereas the lower T_x may indicate easier crystallization made possible by favorable sites for heterogeneous nucleation in locally deformed areas. On the other hand, another part of the glass matrix may suffer from the opposite effect of structural relaxation, leading to an overall lower T_g and a larger heat overshoot of the DSC signal after the glass transition, which is indicative of a more relaxed glass.

5.4 Dynamic Mechanical Properties

Dynamic mechanical properties characterize the resistance of a material to impact loading. For brittle materials, mechanical properties are significantly worse under dynamic than under quasi-static loading. At first glance (Figure 14), this dependence becomes particularly abrupt between 10^3 and 10^4 s^{-1} as illustrated by a Zr-based glass [46]. The difference between the two regimes is that formation of shear bands predominates under quasi-static conditions whereas, as shown by high-speed cinematography, an adiabatic mechanism takes over at higher rates.

The impact fracture energy and stress for the $\text{Zr}_{50}\text{Al}_{10}\text{Cu}_{30}\text{Ni}_5$ glass have been measured with a standard Charpy test on specimens with U-shaped notches [47]. The maximum stress and displacement at the impact fracture are 1615 MPa and 0.44 mm, respectively, and the impact fracture energy is 63 kJ/m². The impact fracture stress is close to the static tensile fracture strength in a wide strain rate range of 10^{-4} to 10^{-1} s^{-1} . However, it decreases rapidly at strain rates higher than about 10^3 s^{-1} . The fracture surface appearance changes from a vein pattern in the region near the U-shaped notch to an equiaxed dimple-like pattern in the inner region.

Figure 14 Schematic representation of strain-rate dependence of the fracture stress of a Zr-Ti-Cu-Ni-Al metallic glass.

5.5 Strain Rate Sensitivity

The strain rate sensitivity of polycrystalline alloys is generally positive, but negative for most metallic glasses under uniaxial compression [48]. The $\text{Zr}_{65}\text{Cu}_{20}\text{Fe}_5\text{Al}_{10}$ glass exhibits a negative sensitivity with a rate parameter m of -0.0026 calculated from the true stress-strain curves [9]. When indentation tests are made, however, an observed positive sensitivity parameter could be mainly attributed to a stress state that is close to those of three-axial compression tests. In this case not a single but several shear bands operate simultaneously.

5.6 Mechanical Behavior of Glass-Crystalline Composites

As seen in strain-stress diagrams, deformation changes leading to a greater plasticity can take place in metallic glasses that bear stress concentrators such as porous and dual crystal/glass materials. An interesting example is that of the dual-phase $\text{Ti}_{42.3}\text{Zr}_{7.7}\text{Cu}_{41.7}\text{Ni}_{7.3}\text{Co}_1$ with

1000 ppm of B where a crystalline $cP2$ phase is embedded in a glassy matrix. Multiple shear offsets are observed on the lateral surface of a compressed sample (Figure 15) [44]. Strain hardening, but hardly detectable serrated flow, was initially observed before small stress drops of 1–3.5 MPa took place after a plastic deformation of 4.5%. Eventually, the material fractured when strain-hardening mechanisms were exhausted in the crystal phase. Hence, the deformation of such a dual-phase material likely takes place through a series of small sample displacements in the shear bands although shear-banding mechanism remains active.

Microstructural toughening and ductility enhancement in metallic glasses and composites actually seem to be a fruitful way to engineer valuable structural and functional materials. The two basic principles involved are: (i) introduction of elastic/plastic inhomogeneities in a metallic glass matrix to initiate local shear banding around them; and (ii) matching of microstructural length scales to the characteristic length scale of crack opening to avoid crack development. Promising results have been obtained in this way on ductile $\text{La}_{86-y}\text{Al}_{14}(\text{Cu}, \text{Ni})_y$ samples with hcp α -La as a dendritic phase as well as on a variety of Zr-based glasses in which the dendritic phase is a body-centered cubic beta-type solid solution. In practice, however, the main problem currently met is that most of such ductile and tough materials made so far are based on expensive elements like Zr, Pt, and Pd.

5.7 Glassy-Crystal Alloys with Transformation-Induced Plasticity

Other structural transformations include deformation-induced crystallization, which can make metallic glasses more plastic. The extent of this plasticization is even more important if a crystal undergoes a phase transformation during deformation. The effect is then similar

Figure 15 Stress and stress drops as a function of plastic strain for the cylindrical $\text{Ti}_{42.3}\text{Zr}_{7.7}\text{Cu}_{41.7}\text{Ni}_{7.3}\text{Co}_1$ crystal-glassy sample with 1000 ppm of B of 2 : 1 aspect ratio upon the compression test. The inset represents a lateral surface of the sample tested to fracture. The diamond symbols denote the stress drop values exceeding 1 MPa. Source: Reproduced from [44] with permission of Elsevier.

Figure 16 Boundary between the amorphous (left) and crystalline (right) phases after deformation of $\text{Ni}_{40}\text{Cu}_{10}\text{Ti}_{40}\text{Zr}_{10}$ glass as seen in by a high-resolution TEM micrograph. Inset: Fourier-transform pattern indexed according to the $mP4$ lattice of the TiNi phase.

to the transformation-induced plasticity (TRIP) of meta-stable austenitic steels and NiTi alloys [9]. The high strength and plasticity of amorphous $\text{Ni}_{40}\text{Cu}_{10}\text{Ti}_{33}\text{Zr}_{17}$ then result from the coexistence of its glass matrix with a $cP2$ ($B2$) crystalline phase analogous to that of austenitic NiTi. Various other composite materials based on Ni–Cu–Ti–Zr glasses have been produced by direct casting into a copper mold [49]. In some other similar composite materials, the martensitic transformation is reversible, leading to superelastic behavior. The structures of the as-cast materials contain a glassy matrix and a $cP2$ ($B2$) (Ni, Cu)(Ti, Zr) crystalline solid solution. Upon plastic deformation, this phase transforms to a $mP4$ ($B19'$) TiNi phase with a lower symmetry and a lamellar morphology (Figure 16). The combination of a hetero-phase structure with the dynamics of the deformation-induced martensitic transformation confers remarkably good strength and plasticity to the composite. The strain–stress relationship of the material (Figure 17) thus shows three different regimes: the deformation is first linearly elastic, then TRIP, and finally indicative of extensive shear- and slip-band formation.

6 Magnetism: Properties and Applications

6.1 Soft Magnetic Materials

Most metallic glasses are non-ferromagnetic but Fe-based glasses have attracted much interest because

Figure 17 The three successive deformation regimes A, B, and C in the strain–stress relationship of the $\text{Ni}_{35}\text{Cu}_{15}\text{Ti}_{33}\text{Zr}_{17}$ alloy after elastic deformation.

Figure 18 A typical magnetization curve of a Fe–Co-based metallic glass.

of the ease with which they can be magnetized and demagnetized. Although, magnetic alloys have long been limited to marginal glass-forming compositions *soft* magnetic properties are achieved in as-cast $\text{Fe}_{56}\text{Co}_7\text{Ni}_7\text{Nb}_{10}\text{B}_{20}$ bulk rod samples (Figure 18), whose coercivity is lower than 10^3 A/m. One of the most promising $\text{Fe}_{76}\text{Si}_9\text{B}_{10}\text{P}_5$ BMG alloy exhibits a saturation magnetization (M_s) of 1.51 T, a coercive force (H_c) of 0.8 A/m, and a critical diameter (D_{cr}) of 2.5 mm [50].

For soft magnetic crystalline materials, H_c increases with grain size (D) with a maximum at about 10^2 nm whereas coarse-grained and nanostructured alloys have lower H_c values. The formation of a nanostructure within a glassy phase thus improves its soft magnetic properties. For example, after annealing at 873 K for 30 seconds, the as-cast $\text{Fe}_{76.5}\text{C}_6\text{Si}_{3.3}\text{B}_{5.5}\text{P}_{8.7}$ glass displays a modified

medium-range order in 1–3 nm zones of its glassy matrix. As a result, the saturation magnetization and permeability (μ) are enhanced from 1.35 T and 3500 to 1.57 T and 9890, respectively, whereas the coercivity is lower than 20 A/m [51].

Compared to other glasses, the (Fe–Co)-based ones are also particularly attractive for engineering applications, thanks to their combination of ultrahigh strength, superior wear resistance, and good GFA with a critical diameter D_{cr} of 2.5 mm. The $\text{Co}_{43}\text{Fe}_{20}\text{Ta}_{5.5}\text{B}_{31.5}$ glass, for instance, exhibits an extremely low coercive force of 0.25 A/m along with a maximum permeability of 550 000. It also has a saturation magnetization of 1.51 T, a coercivity of 0.8 A/m.

Such soft ferromagnetic glasses are now widely used. Licalloy[®] designates those of the Fe–Cr–P–C–B–Si system produced by cold consolidation of atomized glass powders with resin [8]. The Licalloy cores exhibit nearly constant relative permeability in a wide frequency range extending up to several megahertz.

Other soft magnetic powder cores have been developed in cooperation with the NEC TOKIN Corporation from the Fe–Nb–B–Si, Fe–Nb–B–P, and Fe–Nb–B–Si–P systems. The new SENNTIX-II powder cores (Fe–Nb–Cr–B–P and Fe–Nb–Cr–B–P–Si systems) have further reduced core losses [8].

6.2 Hard Magnetic Materials

In contrast, Nd-based glasses show *hard* magnetic properties with a coercivity higher than about 10^4 A/m, which can be used as permanent magnets. Permanent magnets must have a large coercive force, an elevated saturation magnetization, and a high energy product (BH_{max}). The ferromagnetic remanence (B_r), the magnetization under a field of 1242 kA/m, and the coercive force of the bulk $\text{Nd}_{60}\text{Fe}_{30}\text{Al}_{10}$ glassy alloy are 0.110 T, 0.163 T, and 292 kA/m, respectively [52]. The maximum sample thickness for formation of amorphous phase is 6 mm. The $\text{Nd}_{70}\text{Fe}_{20}\text{Al}_{10}$ glass shows ferromagnetism with a Curie temperature T_c of about 600 K. These hard-magnetic properties are presumably due to the development of homogeneous ferromagnetic clusters with a large random magnetic anisotropy.

7 Other Properties and Applications

7.1 Structural and Functional

Other important applications of metallic glasses rely on their excellent mechanical and chemical properties combined with good formability in the supercooled liquid state. These glasses have a smooth surface and soften

on heating at about T_g , which allows the creation of micro and nanoscale patterns on their surfaces by molding. After cooling, the material becomes hard again and can be used as a stamp for others (Figure 19) [53]. Of great interest are also the high elastic-strain limit and fracture toughness ensured by the lack of dislocations and grain boundaries, which make it possible to miniaturize components especially in micro-electromechanical systems. A few examples will illustrate how use can be made of these various features.

Striking application are the 1.5-mm and then the 0.9-mm motor assembled from parts made with Zr–Cu–Al–Ni and Ni–Zr–Ti–Fe–Co–Cu glasses. The former is a three-stage motor whose torque is about 20 times higher than that of the 4-mm conventional vibration motor of cell phones. Likewise, gears made of Zr- and Ni-based glasses have lifetimes 34 and 313 times longer, respectively, than those made with usual tool steel. The micro-g geared motors are being tested for applications to micro-machines, precision optics, and advanced medical equipments such as endoscopes and micro-pumps.

Owing to its high tensile strength and large elastic strain, Ti-based glassy pipes of 2 mm in outer diameter are suitable as sensing elements in Coriolis flow meters used to for gases or liquids in pipes subjected to reinforced oscillations. The sensitivity of such a flow meter is 28–53 times higher than that of the conventional SUS316 pipe [8].

Metallic micro- and nano-wires have applications ranging from interconnectors to sensors. The diaphragms produced by net-shape casting of the Zr–Cu–Al–Ni glasses have been integrated in pressure sensors to achieve much smaller sizes, higher sensitivity, and pressure endurance than with stainless steel.

The AMO-beads[®] powders of the Fe–Ni–Cr–Mo–B–Si glass are used to produce shot-peening balls and fine, precise polishing media by the water atomization process whereby water jets are impinging a falling stream of liquid metal to produce small particles of metallic glass [8]. These balls have much longer endurance times compared with those made with cast-steel and high-speed steels. The AMO-beads are used as shot-peening balls for high-alloy steel to improve its fatigue strength by 50–80% and increase the residual stress on its surface to more than 2000 MPa. Another important advantage is an extremely high resistance to powder explosion reaction in air. Like Fe-based glasses with good soft magnetic properties, they are valuable for micro *mirror actuation*, i.e. extremely accurate positioning of optical components.

7.2 Chemical

Owing to chemically homogeneous composition, lack of grain boundaries and dislocations, metallic glasses with

Figure 19 Scanning electron microscopy microphotographs: (a) and (b) are Si molds, (c–f) are the patterns fabricated with Si molds, (g) is porous alumina, and (h) is the corresponding nanorods fabricated with the porous alumina (g). All the above structures are obtained using molding with the $\text{Pd}_{40}\text{Ni}_{40}\text{Si}_4\text{P}_{16}$ glassy ribbons. Source: Reprinted from [53] with permission of Springer.

spontaneous passivation and low passive current densities have a high resistance against pitting corrosion. In Cr-bearing glasses, this property is, for instance, enhanced by the formation of Cr-rich passive films upon immersion in 1 or 6 N HCl solutions. The corrosion rates of the $\text{Fe}_{50-x}\text{Cr}_{16}\text{Mo}_{16}\text{C}_{18}\text{B}_x$ glasses are within 10^{-3} – 10^{-2} mm/year in 1, 6, and 12 N HCl solutions, respectively. Pitting corrosion does not even take place in a 12 N HCl solution up to a potential of 1.0 V (Ag/AgCl) [54].

Likewise, the passive current densities of the $(\text{Ti}_{0.45}\text{Zr}_{0.1}\text{Pd}_{0.1}\text{Cu}_{0.31}\text{Sn}_{0.4})_{98}\text{Nb}_2$ glass are about 10^{-3} A/m² in phosphate-buffered saline solution. The values of less than 10^{-2} A/m² in lactic acid, and of 10^{-2} A/m² in Hank's solution, are thus lower than those of pure Ti metal, Ti–6Al–4V alloy [55]. The high corrosion resistance of some metallic glasses makes them exceptionally useful for chemical vessels.

Nanostructured metallic glasses represent a new class of materials synthesized from dense packing of nanometer-sized glassy particles (Figure 20). New application in the field of catalysis are opened by Au-based metallic nanoglasses with large surface areas [56]. A good activity has, for instance, been obtained for the reaction of dimethylphenylsilane $[(\text{CH}_3)_2\text{C}_6\text{H}_5\text{SiH}]$ with water to produce the desired dimethylphenylsilanol $[(\text{CH}_3)_2\text{C}_6\text{H}_5\text{SiOH}]$ in 24 hours at room temperature. Another useful chemical application is the degradation of organic pollutants in water like *azo dyes*. The $\text{C}_{32}\text{H}_{20}\text{N}_6\text{Na}_4\text{O}_{14}\text{S}_4$ dye is completely decomposed in an aqueous solution by $\text{Fe}_{73}\text{Si}_7\text{B}_{17}\text{Nb}_3$ metallic glass powders about 200 times faster than with crystalline Fe powders although the glass contains chemically inactive metalloid elements [57].

Figure 20 The structure of a Zr–Pd metallic nanoglass studied by scanning electron microscopy.

7.3 Medical

Two types of medical implant materials have been made from metallic glasses: (i) chemically and biologically inert materials that are not soluble in the human body owing to their high corrosion resistance; for example, glasses of the Ti–Zr–Pd–Cu–Sn–Nb system [55]; and (ii) biodegradable materials consisting of body-friendly metals which dissolve with time so that they do not need to be removed after an operation as exemplified by glasses of the Mg–Zn–Ca ($\text{Mg}_{60}\text{Zn}_{35}\text{Ca}_5$) [58] and Ca–Mg–Zn ($\text{Ca}_{65}\text{Mg}_{15}\text{Zn}_{20}$) systems [59]. The $\text{Ca}_{65}\text{Li}_{6.46}\text{Mg}_{5.54}\text{Zn}_{23}$, $\text{Ca}_{65}\text{Li}_{7.54}\text{Mg}_{6.46}\text{Zn}_{21}$, $\text{Ca}_{65}\text{Li}_{9.96}\text{Mg}_{8.54}\text{Zn}_{16.5}$, and $\text{Ca}_{65}\text{Li}_{14.54}\text{Mg}_{12.46}\text{Zn}_8$ are very light and have good thermoplastic formability close to room temperature but degrade rapidly [60]. Porous metallic glasses can also be used as bio-implants (Chapter 8.4) or damping materials owing to their reduced Young's modulus compared with monolithic metallic glasses.

8 Perspectives

Initially the high cost of elements like gold and palladium seriously hindered practical applications of bulk metallic glasses. The situation thus completely changed when other glasses based on “industrial” metals such as iron, copper, magnesium, and titanium were produced and much bigger pieces progressively obtained (Figure 21). Since then engineers have taken advantage in a great many ways of the strength, hardness, wear resistance, large elastic deformation, and high resistance to corrosion of the new glass families.

From a physical standpoint, Fe-based glasses with good soft magnetic properties are valuable for *mirror actuation*, i.e. extremely accurate positioning of optical components. On the chemical side, Zr–Hf–Ni and Ni–Nb–Zr glasses have a high hydrogen solubility and significant resistance to embrittlement, which make them promising for hydrogen-permeation applications in separators for fuel cells and other membranes. As for nanoglasses, they show unique properties, including enhanced catalytic activity as well as good biological and mechanical properties compared with their homogeneous glass counterparts.

Figure 21 A bulk metallic glass piece: a 5-cm long Zr–Cu–Fe–Al alloy rod.

On the other hand, many questions remain to be solved from a theoretical standpoint. The glass transition has been studied extensively in metallic glasses, but there is still no general agreement on its nature, for instance, on whether it is a purely kinetic or thermodynamic phase transformation. Although equilibrium liquids are homogeneous at a laboratory timescale, there are reasons to believe that deeply supercooled liquids, and the glasses that inherit their structure, are rather heterogeneous in terms of their dynamics. Such heterogeneities in glasses are and will be widely discussed especially in relation to the composition–structure–microstructure relationships, which need to be understood better, for instance, to increase the plasticity and the impact fracture toughness of these materials.

Glass-Ceramics

Monique Comte

Corning S.A.S., Avon Cedex, France

1 Introduction

Glass-ceramics are materials that are first melted and shaped as glass articles and then partially crystallized upon further heat treatment. Depending on the composition of the initial glass, the nature of the crystals formed, and the heat treatments applied, the microstructure of the material can be tailored to specific needs and a wide range of original properties can be obtained. As compared, with vitrification only, crystallization thus opens a large number of possibilities and allows materials with unusual properties to be developed. If glass-ceramics have encountered great commercial success, it is, therefore, because they display a combination of specific properties difficult or impossible to obtain with either a glass or a ceramic.

The best-known products are the low-expansion, transparent glass-ceramics made with lithium aluminosilicates whose applications range from consumer products such as cooktop panels to telescope mirrors. However, other glass-ceramics, such as those based on lithium silicates, display outstanding mechanical strength and good translucency and are used as dental materials. Similarly, glass-ceramics based on micas can be machinable; these are unique and difficult to replace with other materials.

From the research point of view, crystallization remains an intriguing topic. Ever since their discovery in the 1950s, glass-ceramics have been subjected to many fundamental and applied studies in fields such as nucleation and crystallization mechanisms, microstructure, microstructure-properties relationships, and product development in a variety of glass systems. The purpose of this chapter is to review these advances. We will begin with

the history of glass-ceramics and then describe their present uses, processes of production, and main properties. The main composition systems will finally be reviewed.

Even though glass-ceramics are mainly made up of silicates, materials have been developed from other systems. In addition to phosphates, which are dealt with in this chapter, chalcogenides are noteworthy: some of them retain the high transmission in the infrared range of the precursor glasses but display improved thermomechanical properties [1].

2 History and Present Uses of Glass-Ceramics

Because glass is thermodynamically metastable with respect to an isochemical crystalline assemblage (Chapter 5.3), a long-standing problem faced by glass-makers throughout the ages was to avoid partial crystallization when blowing or forming by other means the glass product at temperatures at which the crystallization kinetics may be significant. Partial crystallization thus remained a transformation to be prevented from happening until the physicist and naturalist René-Antoine Ferchault de Réaumur (1683–1757) made and marketed a kind of “China” by crystallizing plain glass bottles upon long annealing in sand ([2], Chapter 10.11). Even though Réaumur’s products were nicely looking and resistant to thermal shock, production had to be discontinued because of low mechanical strength that was itself due to the fact that crystallization was initiated at the surface and ended up being inhomogeneous in the bulk.

Work made much later in Germany by Gustav Tamman (1868–1938) showed that crystallization actually takes place in two different steps of nucleation and crystal growth (Chapter 5.4). Nucleation appeared difficult to

Reviewers: Linda Pinckney, Corning Incorporated, Corning, NY, USA
Edgar Dutra Zanotto, Federal University of São Carlos, São Carlos, SP Brazil

control, however, because it generally takes place preferentially either at the glass surface or in the bulk when defects such as bubbles and batch stones are present. Between 1920 and 1950, glass crystallization via volume nucleation was much studied but the products obtained were difficult to form because the glass tended to crystallize upon cooling in a way that was difficult to control [3].

The process yielding fine-grained crystallization from volume nucleation was serendipitously discovered in the mid-1950s by S. D. Stookey, a Corning researcher, who was studying photosensitive glasses made of lithium silicates doped with low amounts of silver [4]. One night, a thermal treatment of these glasses went wrong when the furnace temperature, which was set at 450 °C, accidentally reached 850 °C. The following morning, Stookey was surprised to discover that, despite this high temperature, the glass had not sagged and did not break when it accidentally fell on the floor. Further analysis revealed that it had crystallized from the nucleating sites provided by the silver colloids dispersed in the volume. Thanks to this experiment, Stookey realized that many glasses could transform into glass-ceramics whose properties would depend on the nature of the crystals formed. This transformation generally requires the presence of appropriate nucleating agents, i.e. of elements that are soluble in the melt at high temperature but precipitate as a multitude of tiny crystals upon cooling and serve as nucleating sites for crystallization of the intended phases.

By the end of the 1950s, Stookey's discovery had led to the development and commercialization of new products by Corning [5]: Fotoform[®] and Fotoceram[®], chemically machinable lithium silicate materials; Code 9606, a glass-ceramic based on cordierite ($\text{Mg}_2\text{Al}_4\text{Si}_5\text{O}_{18}$) used to produce radomes for the aerospace industry (Figure 1); and Corning Ware[®], a material containing the low thermal-expansion phase spodumene ($\text{LiAlSi}_2\text{O}_6$) employed as cooking ware.

Thereafter, research has aimed at increasing mechanical strength and obtaining low thermal-expansion and transparent glass-ceramics [5]. The former effort has led to the development of machinable glass-ceramics and of materials displaying outstanding strength and toughness that resulted from their particular microstructures; an example is Pyroceram[®] tableware. The first transparent products were Schott's Zerodur[®] launched in 1968 (a glass-ceramic with a very low thermal expansion produced for space applications, especially telescope mirrors) and Vision[®] cookware. Beginning in the 1980s, cooktops and fire-resistant windows were subsequently developed. Since then, the diversity of applications has kept growing and the products made of glass-ceramics may be grouped as follows in terms of uses [6, 7]:

Figure 1 Code 9606 glass-ceramic, containing cordierite as main crystalline phase, used as radomes in the aerospace industry (Corning). The height of the pieces range from 0.3 to 1 m.

- Optical applications (telescope mirrors, photonics)
- Consumer applications (cooktops, cookware, etc.)
- Medical applications (bone prostheses, dental restorations)
- Architectural applications (building materials, fire-resistant windows)
- Electronic applications (substrates for electronic packaging, memory disks)
- Energy applications (for example, high ionic-conductivity materials, which could be used as electrolytes)
- Defense applications (for example, transparent armors)
- Technical applications (radomes, machinable materials, and sealing materials)

To illustrate this range of glass-ceramics, representative compositions of commercial materials are listed in Table 1 and their main properties are summarized in Table 2. To complement this picture, the compositions and properties of a few other materials are presented in Table 3, and Table 4 gives the chemical formulas of the main phases mentioned in this chapter.

There are many producers of glass-ceramics. Some are glass companies making specialty glasses (Corning, Schott, Nippon Electric Glass, Ohara, etc.), whereas others specialize in one business (i.e. Ivoclar Vivadent for dental restoration, Eurokera for cooktop). Although glass-ceramics are not widely employed in energy- or environment-related fields, research is very active in these

areas as demonstrated by an abundant literature and numerous patents. Glass-ceramics might, for instance, be used as substrates for solar cells, cathodes for lithium batteries, high-temperature seals for solid-oxide fuel cells, or immobilization of nuclear, industrial, or even municipal waste (Chapters 9.4, 9.5, 9.10, 9.11).

2.1 Formation of Glass-Ceramics

The development of glass-ceramics has long been made on an empirical basis. The detailed mechanisms of crystallization were not known, particularly the first nucleation step, which is either homogeneous or heterogeneous (Chapter 5.4). But much progress has been made recently [9, 10] through theoretical advances, which have concerned glass structure and related topics, and through the variety of analyses made possible by methods such as X-ray diffraction (XRD) and absorption, transmission electron microscopy (TEM), or nuclear magnetic resonance (NMR) (Chapters 3.1 and 3.2).

Homogeneous nucleation is rarely observed in glasses of practical interest. It occurs in phase-separated systems when one of the phases possesses a composition and a viscosity promoting crystallization [6].

An example is mullite ($2\text{SiO}_2-3\text{Al}_2\text{O}_3$), which crystallizes in aluminosilicate glasses: glass droplets of less than 100 nm and enriched in aluminum first form in the glass

matrix, and then crystallize as mullite to yield a transparent material.

Regarding heterogeneous nucleation, two different methods are possible depending on whether the process begins at the surface or in the bulk of the material (Figure 2). Heterogeneous nucleation most simply takes place at the surface of glass frits employed as starting products. With conventional ceramic technologies, a binder is added to the frit to make a paste, which is then shaped to the desired form. Whereas the binder is eliminated by thermal treatment, a further increase in temperature promotes sintering and then surface crystallization. To obtain a nonporous material, sintering must be achieved before the onset of crystal growth, because the presence of crystals increases the material viscosity and prevents sintering [11]. This technique is used to make a variety of products among which cordierite glass-ceramics are used as substrates in electronics, sealing materials, and building materials. An example is the Neoparies[®] glass-ceramic (sold by Nippon Electric Glass), with wollastonite as the main crystalline phase, for which a mix of different glass frits can give a marble aspect to the material.

For triggering bulk crystallization, nucleating agents are generally added to the base glass composition (Figure 2). They are soluble in the molten phase first produced, but not at lower temperatures. On cooling or at the beginning of further thermal treatment, they precipitate as crystallites uniformly distributed in the glass.

Figure 2 The two limiting case of crystal growth in glass [6]. Top: homogeneous nucleation in the bulk (a), followed by the nucleation and growth of the intended crystals on the nuclei (b) to yield the desired microstructure (c). Bottom: heterogeneous nucleation at the glass surface and subsequent inward crystal growth.

These crystallites serve as nucleation sites for the main crystalline phase(s). As described for homogeneous nucleation, liquid–liquid unmixing often plays a role: the nucleating agents can favor unmixing. Further crystallization, either of the nucleating phase or of the main crystalline phases, can then take place in one of the separated phase or begin from the interface.

In every glass system, only a limited number of efficient nucleating agents are available to promote precipitation of the intended crystals. For silicate glasses, these agents can be grouped into three families:

- 1) Oxides such as TiO_2 or ZrO_2 , which are efficient in aluminosilicate systems. They are added in the batch in typical amounts of 2–8 mol %. The crystallites that form include ZrO_2 or ZrTiO_4 in lithium aluminosilicate glass and $(\text{Mg}, \text{Al})(\text{Ti}, \text{Al})_2\text{O}_5$ pseudobrookite in magnesium aluminosilicate glass.
- 2) Fluorine, added as 2–8 mol % fluoride, allows phases containing this element (e.g. fluorides, apatites, micas, or amphiboles) to crystallize in a wide variety of silicate and aluminosilicate systems. The sequence of crystallization is generally complex. A preliminary step of liquid–liquid unmixing is often observed. It is followed by the crystallization of fluorides such as MgF_2 and CaF_2 and then of more complex phases.
- 3) Colloids of noble metals such as Ag, Pt, and Au, which can promote the crystallization of lithium, sodium, or

barium silicates. The metals are generally introduced in ionic form in amounts lower than 1 mol %.

After nucleation, the growth of the main crystal phase (s) is seldom a simple process because, in view of the generally incongruent nature of crystallization, crystal growth requires significant atomic diffusion from the bulk of the glass to the growing crystals, a problem that is compounded when several phases precipitate successively. Another complexity results from the markedly irreversible nature of crystallization at high degrees of supercooling, which tends to cause the precipitation of nonstoichiometric and structurally disordered crystals [12]. A last factor to be considered is metastability that can cause the transformation of the first crystals formed in another phase at higher temperature. A well-known example is the β -quartz solid solution, with which transparent and zero-expansion materials are obtained in the lithium aluminosilicate system, but which transforms to stable spodumene on further annealing above 950 °C. This crystallization sequence is clearly revealed by differential scanning calorimetry experiments (Figure 3).

Industrially, glass-ceramics are manufactured with conventional glass-forming techniques, for example, pressing for cookware, rolling for cooktops, or spin-casting for telescope mirrors. For silicates, appropriate nucleation rates are usually obtained from 50 to 100 K above the standard glass-transition temperature of the starting glass, whereas

Figure 3 Crystal nucleation and growth in a lithium aluminosilicate glass as indicated by the exothermic peaks observed near 740, 825, and 910 °C in a differential scanning calorimetry thermogram recorded on heating at a rate of 5 K/min.

crystal growth takes place at temperatures from 100 to 200 K higher. These two processes thus define two stages in the thermal treatment. The total duration of the thermal treatment can range from a few hours to several months, depending on the kinetics of nucleation and crystallization, and on the size of the pieces.

The processing of Zerodur to obtain telescope mirrors is especially notable in this respect [13] because the challenge is to satisfy tight dimensional requirements for very large pieces with excellent optical quality and uniform zero thermal expansion. For monolithic mirror substrates, the spin-casting process can produce a parabolic shape close to the final concave surface. The maximum size achieved has been 8 m in diameter and required 70 tons of molten glass. In this case, the cooling of the glass lasted three months and the ceramming process more than one year.

3 Properties of Glass-Ceramics

3.1 Microstructure

Glass-ceramics are essentially free of pores. Their properties strongly depend on their microstructure, which, regardless of the nucleation mechanism involved, is constituted of crystals homogeneously distributed in a residual glassy phase [6]. This microstructure can vary widely since these crystals can present different morphologies such as acicular, dendritic, and spherical, whereas their fraction typically ranges from 20 to 90 vol % and their size from 10 nm to a few microns (Figure 4).

3.2 Mechanical Properties

Glass-ceramics are fragile materials as glasses although the presence of crystals can impede crack propagation. Depending on their microstructure, very different

mechanical properties are in fact obtained [5, 6]. Glass-ceramics containing β -quartz solid solutions as the main crystalline phase display a mechanical strength close to that of the parent glass because the crystals have a small size of about 30 nm. On the other hand, some glass-ceramics containing lithium disilicate ($\text{Li}_2\text{Si}_2\text{O}_5$) as the main crystalline phase present a toughness (K_{IC}) in the 2.3–2.9 $\text{MPa}\cdot\text{m}^{0.5}$ range and a modulus of rupture in the 400–610 MPa range. These high values result from the interlocking microstructure of the disilicate crystals. They are at the basis of the use of these materials in dental restoration.

Glass-ceramics containing the fluoro-canasil chain silicate $[(\text{Na}, \text{K})_6\text{Ca}_5\text{Si}_{12}\text{O}_{30}\text{F}_4]$ as main crystalline phase also display an outstanding mechanical strength (Table 3) since a K_{IC} of 5 $\text{MPa}\cdot\text{m}^{0.5}$ and a modulus of rupture of 300 MPa have been reported. Here again the microstructure is highly crystalline and based on interpenetrating blades. The high anisotropy of the thermal expansion of the crystals leading to microcracking is also thought to contribute to the high toughness.

3.3 Optical Properties

As noted above, it is possible to obtain transparent glass-ceramics. To achieve transparency, the mean size of the crystals must be much lower than the wavelength range of visible light. A variety of systems meet this requirement, some materials being highly transparent with a grain size typically lower than 50 nm and crystal fractions as high as 80–90 vol %. The key to achieving tiny crystals then is to form a very high number of nuclei and to limit crystal growth. In cases such as crystallization of BaF_2 in an aluminosilicate glass [14], crystal growth is limited by the formation of a highly viscous glassy layer at the interface of the crystals. The formation of this layer is related

Figure 4 Diversity of microstructures in terms of crystal sizes and shapes obtained in commercial glass-ceramics as observed by scanning electron microscopy (A. Crochet and O. Fraboulet, Corning S.A.S.). (a) and (b) Macor glass-ceramic (main crystalline phase: fluorophlogopite mica) at two different scales. (c) Keralite glass-ceramic (main crystalline phase: β -quartz solid solution). (d) KeraWhite[®] glass-ceramic (main crystalline phase: β -spodumene solid solution). For (a), (c), and (d), the microstructures have been revealed via a chemical attack. For (b), the observation has been made on a fractured sample. For KeraWhite, the pores indicate the former presence of residual glass that has been attacked.

to the depletion of the glass in the more mobile elements, which tend to feed the growing crystals.

To obtain a transparent material, another method would be to match the refractive index of the crystals with that of the residual glass. But, in practice, it is very difficult to satisfy this condition because crystallization is generally incongruent, i.e. the compositions of the crystals and of the residual glass are different. Only a limited number of such materials have been reported. An example is the formation of $\text{Na}_4 + 2x\text{Ca}_4 - x\text{Si}_6\text{O}_{18}$ ($0 \leq x \leq 1$) crystals in a soda-lime glass [15].

Numerous studies have been devoted to optically active materials for applications in the fields of optical communication or solar energy. In this respect, glass-ceramics combine the advantages of a glass phase (i.e. transparency, chemical durability, and ease of fabrication) with those of the crystals into which the active transition-metal or rare-earth ions preferably enter, thanks to the availability of favorable crystallographic sites. Interesting features

such as luminescence or amplification properties have been obtained in several systems, including oxides or oxy-fluorides in which spinels, mullite, and fluoride crystallize, but no product has been commercialized yet [6].

3.4 Rheological and Thermal Properties

As compared with glasses, glass-ceramics offer improved resistance to viscous flow because both the presence of crystals and the preferential partitioning of network-modifier cations into crystalline phase(s) cause viscosity increases that partly oppose the lowering effects of increasing temperatures. The resistance to viscous flow depends on the composition and volume fraction of the residual glass, but materials able to withstand temperatures of 600–900 °C without deformation are common. With alkaline earth aluminosilicates (Table 3), glass-ceramics displaying no deformation up to 1450 °C have been obtained with precursor glasses melted at a

commercially feasible temperature of 1650 °C [6]. In contrast, no rigidification is obtained if the volume crystal fraction is very low. This is, for instance, the case of photochromic glasses, which contain small amounts of silver halides, or of opal glasses containing crystals of sodium fluoride. For this reason, these materials are generally not considered as glass-ceramics.

The bulk thermal expansion of a glass-ceramic is the weighted average of the thermal expansion coefficients of the crystalline and residual glass phases. Because the range of possible values is wider than for glasses, it is possible to tailor the expansion coefficient of a glass-ceramic to specific applications. Glass-ceramics with coefficients higher than $10 \times 10^{-6} \text{ K}^{-1}$ are particularly valuable as sealing materials to metals, for instance, in solid-oxide fuel cells. By contrast, glass-ceramics with almost zero thermal expansion present very high thermal-shock resistance. For example, the Keralite[®] glass-ceramic used as fire-resistant windows withstands thermal shocks of 700 °C (Table 2). On the other hand, β -eucryptite glass-ceramics with negative coefficients as low as $-7 \times 10^{-6} \text{ K}^{-1}$ have even been obtained and proposed as substrates for athermalizing optical fiber reflective grating devices.

3.5 Chemical Durability

Chemical durability is a key property in numerous applications such as consumer products, dental prostheses, and sealing materials. Either through high or low resistance to chemical attack, the specific chemical durability of some crystalline phases and of the residual glass controls the development of numerous products.

For example, the low resistance to hydrofluoric acid of the lithium metasilicate crystals (Li_2SiO_3) allows microstructured materials to be formed by chemical etching (see Section 4.4). On the other hand, the high chemical durability of the zirconolite and pyrochlore phases has led to consider glass-ceramics containing these phases for nuclear waste disposal. The idea is to get the long-lived radionuclides such as actinides preferentially incorporated in the crystals that would be dispersed in a durable residual glass acting as a second barrier of containment.

4 Examples of Glass-Ceramics

4.1 Lithium Aluminosilicate Glass-Ceramics

Products obtained from lithium aluminosilicate glasses represent the main market for glass-ceramics [6, 7]. Their success stems from the combination of several key features, namely, transparency, zero or very low thermal expansion coefficient, and ability to withstand temperatures of at least 700 °C during several thousand hours

without deformation or substantial modification of their properties. They have found a wide range of applications ranging from telescope mirrors to ferrules for optical connectors (produced, for example, by Nippon Electric Glass) or to consumer products such as cooktops, cookware, or fire-resistant windows.

The crystalline phase that yields a transparent low-expansion glass-ceramic is a solid solution with the β -quartz structure. Its general chemical formula is $\text{Li}_{2-2(x+y)}\text{Mg}_x\text{Zn}_y\text{O} \cdot \text{Al}_2\text{O}_3 \cdot n\text{SiO}_2$ (with $n = 2-10$), where Al^{3+} ions replace Si^{4+} in tetrahedral sites and local electrical neutrality is ensured by the incorporation of small ions such as Li^+ , Mg^{2+} , or Zn^{2+} into the channels of the structure (Figure 5). The thermal expansion coefficient of this phase varies from around -5 to $+5 \times 10^{-6} \text{ K}^{-1}$. It significantly depends on composition such that materials with zero thermal expansion are obtained for $6 < n < 8$ when lithium is the main charge compensator.

In this system, TiO_2 and/or ZrO_2 are very efficient nucleating agents. A high number of nuclei of titanates or ZrO_2 form between 700 and 800 °C and then serve as nucleating sites for the subsequent crystallization of the β -quartz solid solution. The best results are obtained when TiO_2 and ZrO_2 are both present in amounts of 1–2 mol %. In this case, a high number of TiZrO_4 crystals form with a size of a few nm, leaving around them a zone enriched in alumina [9]. For reasons not yet fully elucidated, this zone seems to favor the crystallization of the β -quartz solid solution between 800 and 900 °C. The high number of nucleation sites promotes a high level of crystallization of more than 70% in volume while keeping the size of these crystals below 50 nm, which guarantees transparency.

As noted above, the β -quartz solid solution is metastable. It transforms above around 950 °C to a solid solution of β -spodumene ($\text{LiAlSi}_2\text{O}_6$), with which transparency is lost because of formation of bigger crystals as shown by SEM observations (Figure 4). Some of these glass-ceramics with a β -spodumene solid solution as main crystalline phase retain a thermal expansion coefficient lower than $1.2 \times 10^{-6} \text{ K}^{-1}$ and can resist thermal shocks of at least 600 °C, whence their aforementioned uses as cookware or cooktops (Figures 6 and 7).

4.2 Spinel-Based Glass-Ceramics

Spinel with the general formula $(\text{Mg}, \text{Zn})\text{Al}_2\text{O}_4$ are the main crystalline phases in aluminosilicate glasses containing MgO and ZnO instead of Li_2O [8]. Nucleation is also triggered by TiO_2 and/or ZrO_2 . Transparent glass-ceramics are again obtained because the spinel crystals have a mean crystal size of around 10 nm. As most of the network-modifying cations partition into the crystals, the residual glass is highly siliceous and viscous. As a consequence, these materials can withstand temperatures as

Figure 5 Projection along the c axes of the crystal structures of β -quartz (left) and β -eucryptite (right), the two endmembers of a solid solution that form in the $\text{Li}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system [6]. SiO_4 tetrahedra appear in dark gray, AlO_4 tetrahedra in light gray. The lithium atoms can be partly replaced by magnesium or zinc atoms.

Figure 6 Examples of Eurokera products made from glass-ceramics containing a β -quartz solid solution as the main crystalline phase. Keralite glass-ceramic (left) is a transparent colorless material sold primarily for fireplace inserts and stove windows. KeraSpectrum[®] glass-ceramic (right) is sold as cooktop material (courtesy Eurokera S.N.C.).

high as 1000°C without sagging and losing their transparency. With values in the 3 to $4 \times 10^{-6} \text{ K}^{-1}$ range, their thermal expansion is close to that of silicon. Consequently, they have been envisioned as substrates for flat screens or photovoltaic devices.

4.3 Magnesium Aluminosilicate Glass-Ceramics

Cordierite glass-ceramics that are used to make radomes belong to this system. Cordierite has been chosen because it can yield materials with relatively low expansion, high mechanical strength, high elastic modulus, and

transparency to microwave signals used for guidance. In this case bulk nucleation is obtained with TiO_2 [6].

It is also possible to obtain cordierite glass-ceramics via surface nucleation [11]. The process allows strip conductors made of copper, silver, or gold to be encapsulated through cofiring below 1000°C . This method has thus been used to make substrates for electronic packaging as an alternative to Al_2O_3 for which cofiring is performed at 1500°C . In addition to such sintering properties, these materials present the advantage of a low dielectric constant (4–6 as compared to 9 with alumina).

Figure 7 Relative transparency of glass-ceramics produced by Eurokera as indicated by their transmission as a function of wavelength.

4.4 Lithium Silicate Glass-Ceramics

It was with lithium silicates that S. D. Stookey serendipitously obtained the first glass-ceramic nucleated in volume, silver colloids having acted as the nucleating particles. With P_2O_5 as nucleant, one obtains glass-ceramics with very high mechanical strength where the main crystalline phase is $Li_2Si_2O_5$ [5, 6]. These materials are of great interest for dental restoration because they retain some transparency (Chapter 8.5).

Another interesting property of lithium silicates is that their nucleation can be controlled by irradiation (Figure 8) when small amounts of a silver salt and cerium oxide are introduced in the base glass composition. Under irradiation in the 290–330 nm wavelength range, a redox reaction between silver and cerium ions takes place in that silver colloids form while cerium is oxidized. These colloids then serve as nuclei for subsequent Li-silicate crystallization. A mask can limit the irradiated zone over which lithium metasilicate (Li_2SiO_3 , a metastable phase) subsequently forms as fine dendrites. Because lithium metasilicate is highly etchable, it is possible to perform a preferential chemical attack of the crystallized areas and to obtain in this manner a microstructured material. This material is glassy but a glass-ceramic can also be made to increase mechanical strength: for this purpose, an additional irradiation is performed and followed by a thermal treatment in the 800–900 °C range in order to precipitate the lithium disilicate phase ($Li_2Si_2O_5$), which is chemically durable.

These materials are produced by Corning under the names of machinable glass Fotoform and machinable

glass-ceramic Fotoceram, and by Schott under the name of machinable glass Foturan®. With microstructures having a size of 25 μm and a roughness of about 1 μm , these materials are used to make components with a high dimensional precision in the fields of micromechanics, microoptics, and fluidics, for example, where they have the additional advantage of being connectable without any intermediate layer by thermal diffusion bonding. The company Mikrogas has proposed micro-reaction systems for the manufacture of chemical and/or pharmaceutical products made with the machinable glass Foturan.

4.5 Fluorinated Phase Glass-Ceramics

Addition of a few percent of fluorine to silicate glasses allows a wide range of crystals containing this element, such as micas and amphiboles, to be formed. The sequence of crystallization is generally complex. The nucleation mechanism most often begins with phase separation. Crystals such as CaF_2 or MgF_2 then precipitate before transforming into other phases, which give rise to the final microstructure [5, 6].

Among the interesting microstructures obtained with these materials, the interlocking of acicular crystals such as canasite or amphiboles yields outstanding mechanical strength. Another example is the “house of cards” microstructure that ensures machinability in glass-ceramics containing micas as the main crystalline phases and allows materials with a variety of complex shapes to be produced with conventional metal-working tools (Figure 9).

Figure 8 Sketch of the machinable glass Fotoform and machinable glass-ceramic Fotoceram fabrication process. The microstructured glass obtained at step 3 is called machinable glass Fotoform, the microstructured glass-ceramic obtained at step 4 is machinable glass-ceramic Fotoceram.

Figure 9 Examples of pieces produced from machinable Macor glass-ceramic (Corning S.A.S.). Having excellent physical properties, high dielectric strength, and electrical resistivity, the MACOR® glass-ceramic is nonporous, non-shrinking, and withstand high temperatures. In addition, it can be given any complex shapes with conventional metal-working tools.

The trick is that mica platelets are mutually connected and oriented in all directions, thereby isolating pockets of residual glass that represent about 50 s% of the volume of the material (Figure 4). The crystals tend to block and deviate the cracks so that damage is limited to the glass domains. The connection of the crystals gives other advantages to these materials: lack of creep and deformation up to 800 °C, high resistivity, high dielectric strength, and very low helium permeability. Several companies manufacture such materials under the names of machinable Macor®, Vitronit®, and Macerite® glass-ceramics. These materials are used as technical pieces in various domains such as the electronic, semiconductor, or vacuum industries.

4.6 Glass-Ceramics Based on Phosphate Glasses

Phosphate glass-ceramics are mainly used in medical applications and as ion-conductive materials.

In the medical field, two types of applications exist for dental prostheses and bone implants (Chapters 8.4 and 8.5). For dental prostheses, the key properties are mechanical strength, chemical durability, and translucency. A wide range of materials have been commercialized. Among them, glass-ceramics of the $\text{P}_2\text{O}_5\text{--SiO}_2\text{--Li}_2\text{O--ZrO}_2$ system are produced by Ivoclar Vivadent. The content of ZrO_2 exceeds 15 wt %, which is key for mechanical strength.

Requirements for the implant materials are different, in that biocompatibility and eventually bioactivity are necessary. Apatite, $\text{Ca}_{10}(\text{PO}_4)_6(\text{O}, \text{F})_2$, is generally one of the main crystalline phases that form in the phosphate or silicophosphate glass-ceramics used for these applications.

Under the name LICGC™ (lithium-ion conducting glass-ceramic), Ohara sells a material that can be used as solid electrolyte in advanced batteries. The main crystalline phase is a solid solution of Nasicon with the formula $\text{Li}_{1+x+y}\text{Al}_x(\text{Ti, Ge})_{2-x-y}\text{Si}_y\text{P}_{3-y}\text{O}_{12}$ [16]. The high ionic conductivity stems from the structure of the Nasicon phase where the alkali cations occupy sites in interconnected channels formed by corner-sharing tetrahedra and octahedra.

5 Perspectives

Although the history of glass-ceramics is rich in commercial successes, these materials have been developed in the past in a quite empirical way. Nucleation and growth mechanisms were not easy to study because of the complexity of the glass compositions and of the small size of the first nuclei. The important advances recently made in understanding glass structure and in developing analytical methods have considerably increased our knowledge of the nucleation and growth mechanisms in glasses. Such research could be a key enabler for novel materials with outstanding properties. Numerous potential applications can be envisioned. In the future, glass-ceramics will likely serve as key components of products in such demanding fields such as health, energy (solar cell, sealing of solid-oxide fuel cells), and environment (recycling of waste products, including nuclear waste), where materials combining several key properties are required. Research is already very active in these areas.

Section VIII. Organically Related Glasses

Figure 1 The astonishing shaping versatility of biogenic amorphous silica: the shells of some radiolarians drawn by Ernst Haeckel in his famous three-volume book *Die Radiolarien* (1862–1888).

One of the best-kept secrets regarding amorphous silicates is that man is by any standard a negligible maker in comparison with nature: the yearly world production of 120 million tons of glass represents a few per mille of the amount of the amorphous silica synthesized either on land by plants in concretions named *phytoliths* or in the sea by animals like sponges, the *radiolarians* of the zooplankton (Figure 1), and especially by the *diatom* photosynthetic algae. The processes involved appeared relatively late in the evolution history and gave competitive advantages to mechanically strong and optically clear amorphous silica over polycrystalline carbonates whose amorphous forms are highly unstable. As described by J. Livage and P.J. Lopez, this silica synthesis plays a fundamental role in the global cycles not only of silicon but also of carbon and nitrogen; it is taking place under biological control via silanol polycondensation reactions at room temperature, and it has fostered the *biomimetic* design of new materials inspired, for example, by the nanostructured *frustules* of diatoms, with which photosynthetic activity is optimized, or by the fibers of outstanding optical properties of the sponge *spicules* (Chapter 8.1).

In sol–gel processes, the starting materials are liquid organometallic precursors that are mixed at room temperature and transformed into a gel before being dried and sintered in the bulk or as porous pieces, fibers, or thin films depending on the intended application. As explained by R. Almeida and C. Gonçalves, by-passing any treatment at temperatures higher than the glass transition range allows synthesis of markedly metastable glasses that would otherwise unmix or be impossible to deposit on the surface of other materials; practical problems are large shrinkage upon processing or difficulties in eliminating hydroxyl species, whereas the very high cost of the starting products restricts the processes to high value-added products whose market is nonetheless growing rapidly (Chapter 8.2). Special but important cases of sol–gel products are the silica aerogels presented by W. Malfait et al. whose densities can be as low as 0.2 g/cm^3 and thermal conductivities are negligibly small because their nanopores have a size smaller than the mean free path of air molecules; as a result, aerogels are superinsulating materials, whereas their very high specific surface areas of up to $1000 \text{ m}^2/\text{g}$ make them valuable for other uses such as catalyst supports (Chapter 8.3).

An even more rapidly growing field is that of bioglasses. The originality of these new materials is not to be used as permanent prostheses, but rather to stimulate the regeneration of the bone or other tissues by surface reactions that promote natural cell attachment and proliferation. Like for water glass, the key feature of bioglasses discussed by D. Brauer and J. Jones is the intrinsic reactivity of depolymerized calcium- and phosphorus-bearing glasses (produced by melting or sol–gel processes) that

is ensured by their high concentrations of nonbridging oxygens and network modifiers, so these glasses serve as starting materials for spontaneous tissue repair (Chapter 8.4). For dental restoration with onlays, veneers, or bridges, permanent stability is in contrast required. Common glass ceramics (Chapter 7.11) are thus used. As reported by W. Höland and M. Schweiger, the important features engineered with leucite or lithium disilicate glass ceramics are not only high mechanical properties but also ready machinability, resistance to thermal shock, and the possibility to simulate the aspect and hue of teeth with materials that must be clearly distinguishable in radiography (Chapter 8.5).

The rest of the section is devoted to organic glass-forming liquids. As a sequel of the general picture of relaxation given in Chapter 3.7, the contribution by T. Blochowicz, E.A. Rössler, and M. Vogel first describes the additional mechanisms present when the existence of well-defined molecular entities makes rotational degrees of freedom enter the scene; these entities can freeze in at temperatures lower than that of the remaining of the substance and give rise to secondary relaxation processes persisting in the glassy state (Chapter 8.6).

The two following chapters are devoted to organic polymers, which have become the most important glasses in terms of quantities produced. From a mere 2 million tons in 1950, this production reached 335 million tons in 2016 (about 50% in Asia and 20% in both Europe and North America, cf. www.plasticseurope.org) and will keep growing in spite of environmental concerns in particular raised by insufficient recycling in many countries. Compared with silicate glasses, the production is about greater by a factor 3 in terms of mass but of nearly 10 in terms of volume as a result of the large density difference between these two kinds of materials. Although their diversity of uses is not as great, polymers have become indispensable and displaced silicate glasses for many food and beverage containers as well as for high-tech optical applications such as eyeglasses and camera lenses in smartphones (Chapter 6.1). But both kinds of materials complement each other remarkably well in composite materials made up of epoxy resins and reinforcement glass fibers (Chapter 1.6).

In dealing with the physics of organic polymers, J.-P. Cohen-Addad mainly focuses on (i) their very long molecular chains made up of concatenated identical monomers of relatively low molecular mass, within which bond rotation freely takes place in the liquid state; (ii) their viscoelasticity produced by the elastic deformation of the chains and their random motion, which causes viscous flow; (iii) and how the polymer structure can be tailored through partial crystallization or chain cross-linking and may eventually age over the years (Chapter 8.7). Differences in the building, cross-linking, and degree of

polymerization of the various monomers are at the origin of the diversity of polymers and, in particular, of the distinction made between *thermoplastics* (e.g. polystyrene, polypropylene, polyamides, PVC) and *thermosets* (e.g. polyurethane, epoxy, and acrylic resins) depending on whether their curing-induced hardening is reversible or not. Polymerization mechanisms are of two kinds, chain and step growth, as reviewed by O. Weichold who explains how and under what conditions they are controlled in industrial synthesis, why the glass transition temperature is the fundamental theoretical and practical parameter, how it is related to the polymer structure, and how it can be lowered by plasticization (Chapter 8.8).

As exemplified by the aforementioned reinforcement of epoxy resins with glass fibers, composites represent

combinations of different materials at a macroscopic scale such that each keeps its individuality and properties. In the new *hybrid* organic–inorganic polymers described by K.H. Haas and G. Schottner, the combination is in contrast effected at a microscopic level between the structural components of each phase to obtain a homogeneous material combining the advantages of both; owing to a priori structural incompatibilities illustrated by considerable differences in the glass transition temperatures of their components, they must be synthesized via sol–gel processes: the bulk pieces, coatings, powders, and fibers can be produced over wide ranges of fractions of organic and inorganic components with the appropriate starting organometallic precursors (Chapter 8.9).

1 Introduction

Two impressive figures neatly summarize the importance of amorphous silica synthesis by living beings in both aqueous and land environments. For the micro-phytoplankton of the oceans, the yearly silica production is estimated to be 240 Tmol of Si [1] or 15 billion tons – i.e. about 150 times the world glass production – most of which is assigned to a single class of the photosynthetic unicellular algae, the *diatoms*. As for *phytoliths* (from *phutos*, plant, and *lithos*, stone), the silica inclusions present in terrestrial plants ranging from moss, fern, grass, and rice to a variety of trees represent 80 Tmol of Si [2] or 5 billion tons of SiO₂ per year. Given that diatoms account for 35–75% of the marine net primary production [1] and for about 20% of photosynthetic activity on Earth [3], then it becomes obvious that biogenic silica is playing a major role in the global ecosystem. In other words, life has managed to integrate silicon in the metabolism of a great diversity of aquatic and terrestrial organisms, drawing Si from the solute species dissolved in their environments [4].

It has been obvious for centuries that the silica cell walls termed *frustules* (from *frustulum*, small piece in Latin) or *thecae* (sheaths, in Latin) bring protection to diatoms. But the regular and aesthetic pattern of the holes present on frustules was only recently shown to present optical properties [5]. Knowledge about the fundamental aspects of this biogenic production is also relatively recent since the first molecular data were obtained in the early 2000s whereas the biochemical mechanisms of frustule synthesis are only beginning to be understood [6, 7].

Although sponges have much less biological importance than diatoms, some species of these extremely simple animals distinguish themselves by their silica *spicules* whose optical properties rival those of the best commercial fibers [8]. These two examples thus nicely illustrate the interest currently paid to *biomimeticism*, the concept by which attempts are made at imitating the sophisticated nanostructures found in nature to produce new materials with original properties.

Phytoliths, which have also been known for a long time, are lurking in the background of the Si cycle since this element is necessarily transported in plants in the form of water-soluble silicic acid, Si(OH)₄, the starting point for SiO₂ polymerization. The fundamental interest they have recently raised is not related to biomimeticism, but rather to the role of silicon in the nutrition, physiology, and defense of plants [9]. Beneficial effects brought by silicon dioxide, for instance, include resistance against drought, salinity, heavy metal pollution, and other abiotic stresses, as well as against attacks by insect herbivores or parasitic animals and plants. In rice, Si even appears to be actively involved in the plant metabolism.

Biogenic silica thus presents a dual interest either through its biological role or as a material itself. These two features will be addressed in this chapter. A few significant historical aspects of the discovery of biogenic silica will be described first. Next, the production and most outstanding properties and uses of the silica produced by sponges, diatoms, and plants will be reviewed. The stage will then be set to deal with the physical properties of biogenic silica, its condensation from silicic acid, and the mechanisms involved in its synthesis by aquatic organisms and plants from Si dissolved in natural waters and soils at concentrations as small as 10^{−6} mol/l. In the last part, the issue of biomimeticism for green chemistry and nanotechnologies will be addressed along with the

connections between the cycles of silicon, carbon, and nitrogen in the global ecosystem. Finally, fundamental aspects of evolution will be briefly mentioned. Of particular interest are the appearance of biogenic silica and also the advantages that this phase conferred along the evolutionary tree over calcium carbonates, which are actually much easier to synthesize. Although an amorphous calcium carbonate forms as an intermediate reaction step in these syntheses, a marked difference with biogenic silica is the intrinsic instability of this amorphous phase [10, 11].

2 A Slowly Awakening Scientific Interest

In the instance of the *Tabellaria* genus, diatoms were first described in 1703 by an anonymous observer as an *animalcule* [12] in the early days of microscope studies (Chapter 10.10). After diatoms were recognized to be algae in 1844, it was the extreme morphological variety of their frustules that specially drew the attention of naturalists (Figure 1). In the fourth edition of his epoch-making *Origin of Species*, Charles Darwin (1809–1882)

pointed out in 1866 that “few objects are more beautiful than the minute siliceous cases of the diatomaceae” before wondering: “were they only created to be admired under the microscope? The beauty in this latter case, and in many others, is apparently wholly due to symmetry and growth” [13]. At the same period (Figure VIII), the 50–300 mm silica tests of the unicellular *radiolarians* remarkably well pictured by Ernst Haeckel (1834–1919) in his *Die Radiolarien* [14] made so strong an impression on the general public that these members of the zooplankton then served as a model for the entrance pavilion to the famous 1900 Paris World Fair (Figure 2)!

Was Darwin aware in 1866 that the frustules of diatoms accumulating as lacustrine sediments had long been mined as a siliceous source for a variety of uses in the form of *Kieselguhr* (German *Kiesel*, gravel, and *guhr*, wet matter issued from rock)? By a strange coincidence, *Kieselguhr* found a high-tech application when Alfred Nobel (1833–1896) discovered the following year that it was the ideally inert, absorbing porous material needed to stabilize the violently explosive nitroglycerin, which had killed his young brother in 1864. Diatom frustules were thus a key component of his hugely successful commercial product named *dynamite*, to which Nobel Prize winners have owed a great deal since 1901.

Figure 1 The extreme morphological variety of diatom frustules and the specificity of their hole patterns shown by scanning-electron micrographs of a few species among the 100 000, grouped into 200 genera, which are distinguished by their morphology with sizes ranging from 2 to 200 μm .

In Asia, it was the interlocked silica skeleton built by the deep-sea *Euplectella aspergillum* sponge that got some notoriety. In this *glass house* (Figure 3), a male and a female of a small species of crustaceans often live symbiotically with their host. The sponge provides for the food and safety of the couple, which in return keeps cleaning the basket without being able to leave it. Only their offspring are small enough to go out in order to find their own host sponges. One can thus understand why these *Venus flower baskets* were offered as bridal gifts in ancient Japan. However, the remarkable mechanical properties of the meter-long silica *spicules* grown by other sponges [15] have long escaped attention. Likewise, the special optical properties of these silica fibers have been recognized only recently [8].

As for phytoliths, they were assigned antipyretic, antispasmodic, antiparalytic, and (of course) aphrodisiac virtues in Asia in the form of the bluish or yellowish *tabashir* concretions formed in the knots of some species of bamboo. From time immemorial, in contrast, reapers did not know that it was the presence of such tiny, hard inclusions in the soft tissue of grass that required their scythes to be sharpened so frequently. It was the Genevan naturalist

Théodore de Saussure (1767–1845) who noticed the high concentration of silica in the ashes of a wide variety of plants, especially in grass and other ubiquitous Gramineae [16]. Phytoliths were discovered a few decades later by Gustav Adolf Struve (1812–1889) [17] and began to be studied in a systematic way soon after by Christian Gottfried Ehrenberg (1795–1876) [18]. It has then become apparent that they improve not only some mechanical resistance to predators but, as already noticed, also to a variety of stresses in natural environments [9]. With a size typically ranging from 10 to 100 μm , phytoliths also exhibit a wide diversity of shapes, which are species specific (Figure 4). Not surprisingly, phytoliths are much less prone to alteration than their parent plants, even in tropical climates, and may withstand fire and digestion by animals. Thanks to their taxonomically distinctive nature, phytoliths are thus now extensively used in archeology or ecology as tracers of past events. When some carbon is included in phytoliths, an additional advantage is the possibility to perform ^{14}C radioactive dating of their context. To name just a few, topics investigated, thanks to phytoliths, include grass grazing by dinosaurs 70 million years (My) ago, natural shifts in vegetation and climate,

processes and diffusion of plant domestication, or the agricultural practices or diet of populations in most diverse archeological settings [20].

A somewhat related question deals with the biological effects of silica absorbed with the food on human health. There is a quasi-continuum of Si species between amorphous SiO_2 and Si(OH)_4 through di- ($\text{H}_2\text{Si}_2\text{O}_5$), tri- ($\text{H}_2\text{Si}_3\text{O}_7$), pyro- ($\text{H}_6\text{Si}_2\text{O}_7$) silicic acids and higher oligomers. Insufficient levels in Si, which is the third most abundant trace element in the human body, have been related to conditions such as osteoporosis, skin aging, atherosclerosis, Alzheimer's disease, and other degenerative processes [21]. Silicon transport has also been demonstrated to take place in humans, opening the way to new investigations of the physiological role of silicon in vertebrates [22, 23]. A mean daily intake of 12 mg of Si per kg of body weight has been recommended. Cereals, fruits, and vegetables are the most abundant Si sources in

foodstuff. Consistent with the presence of phytoliths in animal dung, however, the bioavailability of amorphous silica and polymeric silicic acids is poor. Phytoliths thus have little prospect of becoming food supplements; zeolites seem to be better alternatives [21].

3 Biogenic Silica

3.1 Sponge Spicules

Sponges are among the earliest and simplest animals. More than 550 million years (My) ago, they appeared during the Cambrian as multicellular aquatic beings devoid of any tissue or organ [24]. Thanks to flagellated cells, they feed on organic matter and bacteria brought by the water that circulates through the 3-D open structure of their pores and canals. If sponges are of course well known for their softness, many species build internal skeletons made up of calcium carbonate or silica. Representing up to 75% of the sponge biomass, the silica skeletons display a high diversity of shapes and sizes. They support the sponges, help during the development along functional body plans, enhance their reproduction success, improve their mechanical strength to endure hydrodynamic forces, and may act as deterrents for predators [25, 26].

The so-called *glass sponges* (*Demospongiae* and *Hexactinellida*) are found worldwide, mostly in deep waters where they grow attached to hard or soft substrates. Their twisted basal stalk is anchored in sediment whereas the upper parts etch a circle by bending and swaying in deep-sea currents. As built around a proteinic axis by cells called *scleroblasts*, their spicules are durable, some of them are flexible, and almost unbreakable. Their sophisticated ultrastructure can involve a 3-D collagenous network that is not only present in the central channel but also extends radially in between the silica layers (Figure 5) [25, 27]. These two components thus give rise to an anisotropic composite material in which the lamellar layers at the spicule periphery connected by bridging organic ligands are effective to stop crack propagation upon bending or twisting. In *Porifera hexactinellida*, the average breaking stress of 593 ± 165 MPa is thus almost four times higher than for pure SiO_2 glass (155 ± 28 MPa) [15]. But the Young's modulus of 36.5 GPa of the former is half that of the latter probably as a result of the weakening effect of the water present in the structure [15]. In subsequent studies, still higher fracture stresses have been observed upon tensile and bending tests, for example, with values of 1895 ± 325 and 3727 ± 661 MPa, respectively, for the 40 μm in diameter spicules of the aforementioned *E. aspergillum* [28].

The spicules of this species in addition exhibit remarkable optical properties. Their distinctive layered design translates into variations of composition and properties within the glass/organic composite as exemplified by the refractivity difference between: (i) a 1–2 μm in diameter Na-doped core with a high index of 1.45–1.48, which may thus be higher than that of silica (1.458); (ii) a 15–25 μm cladding with an index that can be as low as 1.425; and (iii) an outer portion where the index increases progressively from 1.433 to 1.438 [8]. In addition to trap and transport light, spicules can function as single-mode,

few-mode, or multi-mode fibers (Chapter 6.4). These spicules are strong, resist to stress, and form their own supporting elements. Their formation at ambient temperature makes an increase of the refractive index of the fiber possible through the incorporation of impurities such as Na without promoting crystallization. Likewise, residual stresses cannot build up to cause birefringence as often observed in commercial fibers. Finally, the presence of terminal lens-like extensions and barb-like spines along the spicule shaft improve light collection [8]. Spicules may thus be considered as waveguides, which could compete with some of the best commercial optical fibers, to transmit optical, electrical, or even chemical signals, and thus carry information to the cells about their environment. However, the biological role or implications of such light transducing capability are still unknown and very unlikely to occur in most of the natural deep-sea environments within which scleractinian sponges can be found.

3.2 Diatom Frustules

Even if their origin, proposed in the early Mesozoic (250 My ago), from marine or freshwater environments is still a matter of debate [29, 30], diatoms deposits from fresh water dated to the Lower Jurassic (175 My) have been reported. Although their biomass is most significant in the oceans, diatoms are really ubiquitous as they also live in estuaries, rivers, lakes, ponds, puddles, and even in soil or on wetted plants and rocks.

Representing the wall of their cell, their silico-organic frustules are made up of two parts, of slightly different sizes, connected by *girdle bands*. In fact, when diatoms divide during their cell cycle, the new valves (and also girdle bands) are reconstituted within few hours within a specialized cellular compartment, the silica deposition vesicles (SDV). Regardless of their shape, frustules are highly porous to allow for metabolic exchanges with the outside aqueous medium, transparent to light, and also rigid in order to protect the cell against predators (mainly grazing *copepods*, i.e. small herbivorous crustaceans). Indeed, the frustules of living diatoms exhibit outstanding mechanical properties. For example, the oval-shaped frustules of *Fragilariopsis kerguelensis*, the most abundant species in Antarctic seas, can, for instance, sustain estimated maximum stresses of 540 MPa whereas the ultimate tensile and compressive stresses of the valve and girdle are 560 and 680 N/mm² and 155 and 330 N/m², respectively [31]. Although their Young's modulus of 22.4 GPa is lower than that of pure silica glass (73 GPa), it is close to those of cortical bones (20 GPa) and dental composites (6–25 GPa) [31–33]. This feature is likely one of the reasons why diatoms have been biologically so successful compared with other algae.

Some silica frustules exhibit a hierarchical distribution of pore sizes. The genus *Coscinodiscus*, for instance, exhibit three layers of pores containing small (≈ 10 nm), medium (≈ 100 nm), and large pores ($\approx 1 \mu\text{m}$) (Figure 6). These pores are not randomly distributed but rather ordered in a periodic 2-D network with a basal spacing of few tenths of microns (Figure 7). Diatom frustules exhibit iridescence and are often referred to as “sea opals” with the important feature that they focus visible light while reflecting UV rays [5, 34–36].

Figure 6 Scanning electron micrograph revealing the hierarchical distribution of pores on the frustule of *Coscinodiscus* sp.

Figure 7 The 2-D periodic network of *Coscinodiscus* sp.

After dying, diatoms sink and escape dissolution in part, thanks to the organic materials, and can then accumulate as beds interspersed with other. Once deposited, the frustules slowly compact and transform into *diatomite*. In the process [37], the 3-D network structure of amorphous silica develops through a decreasing fraction of Si atoms bearing silanol groups (Si-OH) and a concomitant increase of the fraction of Q^4 species (Chapter 2.4). Already known in Antiquity, diatomite is a rather pure, inexpensive, and soft raw material widely exploited in open-pit mines (Figure 8). It mainly consists of wet amorphous silica, but also contains up to 3% of quartz. The extracted product is gently crushed, dried, and milled and, depending on purity and use, it can be calcined between 850 and 1000 °C in large rotary kilns to remove moisture and organic products. Upon calcination, up to 40% of the amorphous silica can transform into cristobalite, the high-temperature SiO₂ polymorph. The proportion can even reach 70% when soda ashes (sodium carbonate) are used as a flux to promote sintering during calcination. After calcination, the generally whiter product is crushed and sifted in different categories depending on the grades to be commercialized.

The main producers of diatomite in 2016 were the United States (850 kton), Czechia (450), China (420), followed by Argentina (200), Peru (150), Japan (100), Mexico (90), France (75), and Russia (70). The rest of the world accounts for 220 kton. Because of its chemical inertness, large specific surface area, and tiny pores of the frustules, diatomite is used in thousands of common products. It is best known as an excellent material for liquid filtration in the pharmaceutical industry, breweries, wineries, or swimming pools. In addition to stabilizing dynamite, it serves as catalyst support; a filler in paper; paints or plastics; an absorbing agent for oil, grease,

Figure 8 Diatomite exploitation in an open-pit mine at Foufouilloux (Cantal, central France). Frustules accumulated during 50 000 years at a rate of 0.3 mm per year in the 800 × 1300 m lake of an explosion crater formed 5 million years ago. It was then filled with clear, cold, and relatively Si-rich waters that were particularly favorable for diatom growth. Source: Photo P. Richet.

hazardous waste, or in animal litter; a light component in concrete; a soft abrasive in polishing, etc.

From an anecdotal standpoint, one can finally note that the huge variety of diatoms and the specificity of their habitats have led them to be valuable for identification purposes. To quote the single example of forensic medicine, diatoms make it possible to determine whether or not the species found in the lungs of a drowned person are actually those of the water expanse where the body was found even long after death.

3.3 Phytoliths

To begin with mosses, which date back to the Cambrian, phytoliths are produced in most plant groups with the exception of conifers, ginkgo, many cycads, and other gymnosperms [38]. The reason why their shapes are generally specific to the species considered (Figure 4) is that they deposit preferentially in the free spaces of the vascular systems of the plants. Because phytoliths are also found in epidermal cells and in *stomata*, the pores of the leaves or stems through which gas exchange takes place with the atmosphere, coupling of biomineralization with transpiration is commonly assumed [39]. Silicon is in fact the only element that is not toxic for plants at any high concentration. Terrestrial vegetation can accumulate various amounts of this element, ranging from 0.1 to 10% of dry weight depending on whether they reject or accumulate it passively or actively [2]. After having contributed to the rigidity of the plant and its defense against various stresses, phytoliths accumulate in the soil when plants die or leaves fall. Biogenic silica is 7–20 times more soluble in water than silicate minerals. Phytoliths then control the silicon content of porous soil and draining rivers. They improve the quality of soils through clay formation with the silicon species available [40].

From an economic standpoint, particularly important is the silica accumulating in the hard, covering husk (or hull) of rice that protects it against attacks by insects and bacteria. Representing about 20% by weight of the

harvested crop, the husk itself consists of cellulose ($\approx 35\%$), hemicellulose ($\approx 25\%$), lignin ($\approx 20\%$), proteins ($\approx 3\%$), and “ashes” ($\approx 17\%$) whose silica content is about 94% [41]. In view of the 750 million tons of rice yearly produced, the silica obtained could amount up to 25 million tons if the husk were wholly burned. Its main impurities are K_2O , CaO , and Al_2O_3 at levels that can be 1% or higher, depending on soil type, fertilizers used, and climatic conditions [41]. Upon calcination, not only the composition but also the mineralogy and the microstructure of silica obtained depend on possible pretreatments, temperature, duration, and combustion atmosphere. Amorphous silica with a purity higher than 99% and a particle size in the 0.5–0.7 μm range can, for instance, be obtained after leaching the husk with HCl and H_2SO_4 acids [42]. On the other hand, the proportion of cristobalite increases with increasing combustion temperatures whereas trace of tridymite can also be found.

The composition and properties of rice hull ashes (RHA) depend on so many factors that only a few of their uses will be mentioned here. As already noted, they are a potential source of amorphous reactive silica. They have become a starting material for the preparation of silicon and silicon compounds such as silicon carbide and silicon nitride [43]. They are also used for the simultaneous preparation of silica and activated carbon with a high adsorption capacity [44] or as additives in the production of cements where the fine silica particles provide a very compact concrete [45]. The fitness of RHA makes them very good candidates for sealing fine cracks in civil engineering structures. They can penetrate deeper than the conventional cement sand mixture. They also exhibit good thermal insulation properties.

It is also possible to convert silicon dioxide into silicon through a magnesio-thermic reduction process while maintaining the relative morphology of the initial material. Pure Si nanoparticles (SiNPs) can be derived directly from rice husks (RHs) with a conversion yield as high as 5% by mass. Owing to their small size (10–40 nm) and porous nature, these SiNPs are expected to increase the

performance of Li-ion battery anodes [46–48]. Taking advantage of the interconnected nanoporous structure naturally existing in RHs, the converted silicon exhibits excellent electrochemical performances. It could provide a theoretical specific charge-storage capacity 10 times higher than that of conventional graphite anodes, which would make RHs a massive resource for the anodes of high-capacity lithium batteries [49]. Finally, biogenic silica particles could also be useful for pharmaceutical purposes as inhibitors of human breast-cancer cell lines and drug delivers for folic acid [39].

4 The Low-Temperature Silica Factories

4.1 Silica Condensation

Whether in an aqueous or a terrestrial environment, a major feature of the formation of biogenic silica is the way in which a rather pure silica substance is synthesized from very low concentrations of dissolved silicon species. In shallow sea waters, the total Si concentration is, for instance, a few $\mu\text{mol/l}$ [50], which implies that extremely efficient biological mechanisms have evolved to concentrate silicon species and precipitate them as amorphous SiO_2 .

Silica is slightly soluble in water (0.14 g/l). Under ambient conditions, its dissolution gives rise to silicic acid:

Depending on pH, more or less deprotonated species can then form, ranging from $(\text{H}_5\text{SiO}_4)^+$ at low pH to $(\text{H}_2\text{SiO}_4)^{2-}$ at pH higher than 10.

The reverse reaction occurs upon silica formation. It represents a condensation reaction between two silanol groups leading to the formation of an oxo-bridge between 2 (SiO_4) tetrahedra:

The overall polycondensation reaction can thus be written as:

Small particles form first and then grow in size to yield colloidal solutions (sols) and gels (Chapter 7.5). *In fine* an amorphous SiO_2 , $n\text{H}_2\text{O}$ hydrated silica network is obtained whose nucleation and growth rates depend on the particular physicochemical conditions. The final 3-D network is in particular influenced by factors such as salinity, pH, and, to a lesser extent, temperature [51]. Silica fibers form at low pH whereas colloidal particles

are obtained under basic conditions. These particles are commercially known as *Stöber silica*. Known as *sol-gel* process, these inorganic polymerization reactions are nowadays widely used in the glass industry. Their main advantages over usual melting are to make powderless processing of glasses and ceramics possible, to synthesize highly metastable phases and organic or bio-hybrid materials, and to deposit a variety of amorphous thin films (Chapters 6.8, 8.2, and 8.9).

4.2 Silica Formation in Aquatic Organisms

As a prerequisite to biomineralization, silicic acid must be transported into the cells where condensation might occur. This transfer of silicic acid was first deciphered in the late 1980s through tracer experiments made with the short-lived radioisotope ^{68}Ge to study the expression of a gene coding for a silicon-transporter (SIT) protein isolated from a diatom in ovocytes of *Xenopus laevis* (an amphibian widely used as a model system in biology) [6]. These sodium-coupled active transporters are made up of 10 transmembrane segments. As usually done for characterizing the kinetics of an enzymatically catalyzed reaction, the initial rate transfer is related to the concentration of the substrate and characteristic parameters of the enzyme. These parameters determined *in vivo* for Si transport in different marine and freshwater diatoms point to a high affinity of the SITs for silicic acid with half-saturation constants (K_s) in the 0.2–7.6 $\mu\text{mol/l}$ range. Other mechanisms, such as the transport of the deprotonated form $\text{SiO}(\text{OH})_3^-$ by SITs or the diffusion of $\text{Si}(\text{OH})_4$, have been proposed as alternative routes for the uptake of silicic acid.

Diatoms actually possess multiple SITs. The expression of this multigene family is regulated by the availability and concentration of silicic acid in the medium and by the period of interest during the cell cycle. In this respect, an interesting feature is that similar genes have been identified in other silica-producing species, the *Synurophyceae* algae as well as in the unicellular loricate Choanoflagellates [52]. Such a homology in protein primary structure is thus suggestive of putative transfer of genes both horizontally and vertically throughout evolution.

The formation of silica structures involves organic molecules although complete information on their diversity, concentration, and precise role in the polycondensation process is still missing. In diatoms, several proteins associated with the silica frustules have been identified [7]. *Silaffins* are, for instance, rich in serine ($\text{C}_3\text{H}_7\text{NO}_3$) and lysine ($\text{C}_6\text{H}_{14}\text{N}_2\text{O}_2$) amino-acid residues and harbor a high number of post-transcriptional modifications (i.e. phosphorylated, glycosylated, sulfated). Other proteins are also involved in the regulation of the polycondensation process of the valve diatom silica thecae (i.e.

silacidins, cingulins, silicanin, silicalemna-associated proteins). The other kinds of biomolecules embedded within diatoms thecae are long-chain polyamines (LCPA), polysaccharides (i.e. chitin), and lipids.

The morphologically aesthetic but complex biosilica structures formed by diatoms are assembled within the aforementioned SDV. The confinement of amorphous precursors within such specialized membrane-bound compartments allows various features to be controlled: (i) the physicochemical conditions of the polycondensation process (i.e. ions concentration, pH regulation) that are likely to be key issues [53], (ii) the dynamics of incorporation of the organic and mineral fractions, (iii) specific targeting of proteins and molecules to the SDV compartment, and (iv) the 3-D assembly. Several biophysical models have been proposed to explain the regular nanopatterning of biosilica, such as a phase separation process, diffusion-limited aggregation, or even mixed models [54–56].

In sponges, spicules deposit as concentric silica layers around a central proteinic filament. The sponge cells absorb minute traces of silicic acid from sea water and use it to produce a monolithic amorphous silica rod by such a concentric deposition involving an enzyme called silicatein [57]. As already described, small spicules are then extruded from the cell and grow via silica deposition to produce the fibers that serve to anchor the sponge to the deep-sea floor.

4.3 Silica Formation in Plants

The presence of Si within the plant originates in its uptake from the soil in the form of soluble $\text{Si}(\text{OH})_4$ or $\text{SiO}(\text{OH})_3^-$, and then of its controlled polymerization at the final location. Soluble silica from ground water is absorbed by the roots and carried to different parts of the plant by the sap through the vascular system. The first silicic-acid transporter in land plants was identified in a study of a rice mutant (*Oryza sativa*) defective in silicon uptake. The controlling gene, named *Lsi1* (Low-silicon rice 1), which encode a protein belonging to the aquaporin family, is constitutively expressed in the roots. A homolog of this *Lsi1* gene, *Lsi6*, causes the intervascular transfer of Si and is involved in the deposition of silica in leaf blades and sheaths. As also demonstrated in rice, the efflux of silicon from the root cells involves the *Lsi2* gene [58]. After take up, silicon is deposited on cell walls as a polymer of hydrated, amorphous silica to form silica–cuticle and silica–cellulose double layers on the surface of leaves, stems, and hulls. Homologs of *Lsi* genes have been found in several other Si-accumulating plants as diverse as maize (*Zea mays*), barley (*Hordeum vulgare*), sorghum (*Sorghum bicolor*), wheat (*Triticum aestivum*), a

Cucurbitaceae species (*Cucurbita moschata*), soybean (*Glycine max*), and horsetail (*Equisetum arvense*) [59].

Even though Si absorption pathways present similarities in mono- and dicotyledons, our understanding of the protein domains involved in Si-recognition remains rudimentary. Further studies are also needed to address intracellular Si accumulation, subcellular transport, and deposition. We do not know yet when and how the biological cycle of silica evolved. Because it seems to couple with transpiration process and antioxidant activities, however, it should have been an important process for land plants for over 400 My [38].

5 Biomimetism and Applications

Diatom frustules can be considered as novel biofunctional materials, thanks to the large diversity of potentially useful nanostructures in many areas of application [60, 61]. The biomimetic routes investigated involve either the thecae themselves or chemically modified replicates or, alternatively, the use of organic compounds extracted from their biosilica to develop strategies for protein encapsulation or biosensors [62, 63].

Frustules have thus been used for the realization of gas sensing devices based on the photoluminescence (PL) properties of silica, which emits a blue light ($\lambda = 500$ nm) upon UV irradiation at 325 nm. Frustules of a few microns in diameter can be mounted onto the tip of an optical fiber. The position and intensity of the photoluminescent emission peak then depend on the presence of different gases or vapors (e.g. NO_2 , ethanol, or acetone).

Silica frustules have also been used as templates for the realization of 3-D nanostructured materials. The so-called Bioclastic and Shape-Preserving Inorganic Conversion (BaSIC) method was introduced to transform the biosilica frustule into another material while maintaining the original structure. Mesoporous oxides such as MgO , TiO_2 , ZrO_2 , and BaTiO_3 have thus been synthesized with a diatom microstructure. For example, gas/silica displacement reactions, such as magnesio-isothermic reduction, lead to the formation of MgO frustules with fine nanoscale structures. The whole silica frustule can even be reduced into silicon in the form of nanostructured Si materials to open new possibilities in electronics. Insertion of TiO_2 or GeO_2 into the nanostructure is another way that has been proposed to produce LED devices (Chapter 6.9), battery electrodes (Chapter 9.5), or dye-sensitized solar cells [64, 65]. Alternatively, *in vivo* incorporation of foreign elements such as Ge can be obtained upon addition of $\text{Ge}(\text{OH})_4$ to the growth medium of

diatoms. In this way, a homogeneous distribution of Ge atoms is achieved in the silica frustule, providing a typical blue luminescence although one should not lose sight of the fact that germanium is a toxic element for diatoms.

Concerning spicules, yet another of their unique properties is their triboluminescence as discovered in the composite organosilicon materials of *Hexactinellid* sponges. These might contribute to the creation of biomimetic materials capable of emitting light, which, in turn, might be used in various devices for the transformation of energy.

6 Biogenic Silica in the Global Ecosystem

6.1 Silicon Cycle

The silicon cycle in Earth ecosystems is regulated on the one hand by the release of this element upon alteration of silicate minerals and, on the other, by its incorporation in phytoliths on land and in the frustules, spicules, and other silica biominerals in natural waters. On land and at sea, the production of silica is of course tightly related to that of organic matter so that the global cycles of silicon, carbon, and nitrogen are themselves strongly coupled. It, for instance, follows that anthropogenic pressures might in the long-term impact the silicon fluxes from inland waters to coastal systems and, thus, the overall primary biological productivity in these areas. Because of river damming, the concentrations of N and P are, for instance, increasing with respect to that of Si, which could adversely affect diatoms, but the opposite effect of an increased Si flux would result from deforestation, modifications of agricultural practices, and increasing urban populations [2]. Even though it is not easy to estimate the actual balance between such effects, it appears that plant silica plays a key role in connecting the terrestrial and marine carbon cycles.

Of particular importance in this respect are the algae of the phytoplankton, which are at the basis of the most productive oceanic food chains and are also the main agents contributing to the *biological pump* through which carbon is transferred from the surface to the deep ocean. When diatoms die, it was commonly assumed that their carbon content was readily degraded into CO₂ during their fall before reaching depths of about 1000 m. But recent studies have highlighted that the recycling of carbon mainly occurs much deeper at the sediment–water interface. All species do not have the same efficiency in this respect, depending on their size, shape, and Si/C ratios of the frustules and also on their biogeochemical environment. It has nonetheless been estimated that the residence time of carbon at depth is longer than a

century [66]. By comparison, the average residence time of silicon in modern oceans ranges from 15 000 to 17 000 years, suggesting that the silica cycle is currently in a steady state [67].

On a global scale, the contribution of other siliceous protists (i.e. radiolarians, silico-flagellates, etc.) is much less important. But several marine eukaryotic organisms, like siliceous sponges might have an overlooked but non-negligible importance in the Si cycle in specific areas such as continental shelves.

6.2 Silica Versus Calcium Carbonate

The first calcareous deposits known as *stromatolites* began to be made by bacterial colonies 3.7 billion years ago. Ever since the Cambrian (570 My), other biogenic carbonates have been produced in phototrophic, heterotrophic, and autotrophic organisms as diverse as red, green, or brown algae, *cnidaria*, *brachiopoda*, *mollusca*, or *crustacea*, often in close association with chitin [(C₈H₁₃NO₅)_n], a long-chain polymer made up of a derivative of the glucose (C₆H₁₂O₆) sugar. In seawater, the biological formation of either calcite or aragonite, the two main CaCO₃ polymorphs, would not appear to represent a feat. The CO₂ pressure of the primitive atmosphere was, for instance, high and the concentration of Ca²⁺ ions has since then remained high enough in sea water that, with an average value of 0.01 mol/kg, calcium carbonates are actually oversaturated at depths lower than about 2000 m. Precipitation of CaCO₃ polymorphs is not direct, however, but takes place through the dehydration of an amorphous calcium carbonate precursor. That this precursor is usually unstable is not surprising since molten CaCO₃ is not at all a glass-forming liquid. Would it then be possible to interpret the remarkable success of diatoms in terms of the advantages of frustules made up of amorphous silica instead of calcite or aragonite?

7 Perspectives

Climate is not the only factor influencing biological producers of silica. That radiolarians were more abundant in a distant past was probably the result of higher Si concentrations in seawater caused by a strong volcano-hydrothermal activity during periods of major plate-boundary reconfigurations. The ubiquitous nature of diatoms and their predominance in cold and turbulent waters of the oceans has long been established, thanks to their particularly efficient way of handling the aqueous silicon species available at a low energy cost. Except in Austral seas, this predominance might be threatened if warmer and stratified oceans were to prevail in the future.

In that case, however, one cannot exclude that diatoms would be able to adjust successfully to new conditions that would include more acidic waters.

As a matter of fact, much remain to be learned concerning not only the synthesis of biogenic silica, but also the way in which their producers interact with their environment or how the silica-armored preys and their predators coevolved. At a most fundamental level, the manner in which Si transporters have evolved has still to be deciphered. It nonetheless appears that both SIT and Lsi2 transporter families are found in different lineages, which suggest that they originated in a distant Precambrian past when oceanic Si concentrations were much higher than today [68]. It has thus been surmised that Si transporters might have first evacuated toxic Si at high concentrations from the cells before serving instead a biomineralizing role. However, the true role of silicification in cell detoxification might need deeper investigations. Silicon transporters might have not only various origin (e.g. aquaporin-related sequences in plants and humans, and SIT-related sequences in fresh and marine water diatoms, chrysophytes, silicoflagellates, dinoflagellates, haptophytes, ciliates and choanoflagellates, and in bacteria), these transporter families might have been acquired independently, but also suffered lost in several lineages, duplication, and sub-functionalization events. Therefore, a better understanding of the evolution of silicon transporters and of the expression and regulation of these genes is likely to have significant implications on our understanding of the capabilities of these organisms to cope with environmental changes, and implicitly on the human impacts on several biogeochemical cycles.

In materials science, biogenic silica has opened wholly new areas. Beginning with a few pioneering studies three decades ago (e.g. [69]), rice-husk valorization has, for instance, become a very active field of research. Another rapidly expanding domain is that of bioinspired glasses. As already noted, porous diatom frustules can, for example, be used as precursors for the production of nanostructured materials such as photonic crystals. On the other hand, sol–gel processes are already extensively used industrially in many applications such as the production of coatings, fibers, and nanoparticles (Chapter 8.2). The *soft* conditions associated with the production of these glasses have led to the design of hybrid organic–inorganic materials in which both organic and inorganic species can be mixed at a molecular level ([70], Chapter 8.9). A further development already under way consists in trapping biomolecules such as enzymes or even whole cells within these new materials to form “living materials” [71, 72] but there is little doubt that this approach will give rise to unexpected new products and processes in the next decades.

8.2

Sol-Gel Process and Products

Rui M. Almeida and M. Clara Gonçalves

Departamento de Engenharia Química, CQE, Instituto Superior Técnico, Universidade de Lisboa, Lisboa, Portugal

1 Introduction

To synthesize amorphous or crystalline materials at relatively low temperatures, sol-gel methods are based on colloidal chemistry processing, involving the preparation of a colloidal suspension (sol), the gelation of the sol, and the removal of the liquid existing in fine interconnected channels within the gel. The product is then dried, for instance, at a temperature as low as about 100 °C. The dry gel is still porous, so it must be finally sintered at a temperature close to the glass transition (T_g) if a dense glass is to be produced, or it can be used in the form of a porous material.

This technology is an alternative to traditional melting and quenching for glass preparation that is especially suitable for the deposition of coatings. But the sol-gel technology can also be used for the fabrication of glasses in bulk, nanoparticle, powder, or fiber forms, which have structures virtually identical to those of melt-quenched glasses of the same compositions. The process is used to prepare ceramic materials as well, which include one or more crystalline phases. Some of these may be glass-ceramics obtained by the controlled crystallization of sol-gel-derived glasses [1].

The sol-gel process can claim a long history since the first (casual) observation of the hydrolysis and polycondensation of silicic acid dates back to the work of Jacques-Joseph Ebelmen (1814–1852) in 1846 [2]. But practical use of such reactions had to wait almost a century when Geffcken and Berger in 1939 synthesized SiO₂ glass layer glass from gels [3], whereas the first multicomponent silicate sol-gel glasses were prepared by Della and Rustom Roy in 1955 [4]. The growing interest of many researchers in the method became apparent only

in the mid-1970s, however, particularly when the work of Dislich [5] opened new synthesis routes of oxide glasses and thus triggered an ever-growing number of potentially attractive applications. Considering the preparation of multicomponent oxide glass coatings on suitable substrates, with application such as protective layers against oxidation and weathering, the first commercial products were probably automotive glass coatings (antireflective) developed by Schott Glass Works in the 1950s, based on alternating silica glass and titania sol-gel-derived layers. This expansion was also fostered by the decreasing cost of precursor chemicals, which was one of the initial impediments to many applications, as well as by increasingly reproducible processes.

At present, sol-gel processing is used to prepare a large number of amorphous and glassy materials, particularly functional coatings for many different purposes, as well as other types of inorganic and *hybrid* (organic-inorganic) coatings on glass, sometimes partly or even fully crystalline, and aerogels (Chapter 8.3). Many companies utilize it nowadays even when it is not their core business. Some of the important industrial companies in the field include Schott (Germany), the Donnelly Corp. (USA, optical coatings), Denton Vacuum Inc. (USA, optical coatings), Aspen Systems (USA, aerogels), Geltech (USA, optical components, porous substrates, and powders), Hybrid Glass Technologies (USA), and Nanogate Technologies (Germany), specialized in hybrid sol-gels, SIMAX Technologies (USA, fiber optics, microlenses, etc.), Sol-gel Technologies (Israel, health care products), and Chemat Technology Inc. (USA, precursors and processing equipment).

In this chapter, we will thus begin with details of the most representative sol-gel chemistry and forming processes, concerning the most important inorganic and hybrid materials that are currently prepared. We will then summarize the main advantages and drawbacks of the process at present, before describing products and applications, from

Reviewers: B. Dunn, Samueli School of Engineering, UCLA, Los Angeles, CA, USA

M. Guglielmi, Industrial Engineering, Università di Padova, Padova, Italy

zero-dimensional (0-d) nanoparticles to 3-D bulk glasses and finally pointing to new features of sol-gel science and technology that are likely to gain momentum in a near future.

2 Sol-Gel Processing

2.1 Basics of Sol-Gel Processes

Conversion of a solution or a sol into a dense material requires the following steps:

Sintering is not included in this flowchart because it is an optional step, necessary for making eventually a glass, but occasionally absent, particularly when organic groups are designed to be present in the final (hybrid) product (Chapter 8.9). The chemistry consists of reactions involving colloidal particles in a sol, or between alkoxide-derived polymeric species and water in a solution, leading to a highly porous amorphous gel network, where a liquid phase (solvent, catalyst, and eventually excess water and precursors) may be retained. During drying and sintering, the open network typically undergoes at least 50% linear shrinkage caused by removal of the liquid phase and drastic reduction of the porosity, ultimately forming a dense sol-gel material (inorganic glass or ceramics). Depending on several interrelated experimental parameters, a wide range of microstructured products may be obtained (Figure 1). These include (i) inorganic or hybrid coatings on a substrate, for which the process is a highly convenient technique that starts at ambient temperature and pressure; (ii) hollow, dense, porous, or structured nanoparticles; (iii) high-purity powders from which

dense ceramics can be obtained via sintering; (iv) very low-density aerogels obtained by supercritical drying of wet gels and rather difficult to prepare by other techniques; (v) and fibers, which can also be fabricated, although the technology is not the best available in this case.

2.2 Inorganic Sol-Gel Materials

In the *colloidal route*, colloidal particles are formed in an aqueous medium from ionic species according to the principles of colloidal chemistry. In the case of silica, for example, the ~1 nm SiO₂ particles present in sols of dilute silicic acid undergo rapid growth up to 2–4 nm at pH 2–3. As described below, the silica solubility increases so much above pH 7 that the particles grow up to 4–6 μm by coalescence and Ostwald ripening. Monomeric silicic acid then helps cementing the nanoparticles to form a bulk gel.

The most common synthesis process, however, involves the *polymeric route*, which may also be exemplified with silica. Here, metallic salts, metal alkoxides, or other more complex organometallic precursors undergo hydrolysis and polycondensation to form the gel. Because of the hydrophobic nature of the alkyl groups, organometallic precursors and water are not miscible, so that addition of a common solvent (usually an alcohol) becomes mandatory to promote miscibility between the reactants. In the most common case where an alkoxide is used as precursor, the alkoxide molecules in solution undergo hydrolysis, usually with the help of a catalyst, either an acid or a base.

Acid catalysts – usually HCl, HNO₃, or CH₃COOH – are thought to promote hydrolysis by electrophilic attack. The rate of hydrolysis increases with the decrease in pH, starting from 7; meanwhile, the condensation reaction rate exhibits a local minimum at the silica isoelectric point at pH 2. Acid-catalyzed sols exhibit longer gelling times than base-catalyzed ones, yielding gels with a large volume shrinkage. When a base, such as ammonia, is selected instead as a catalyst, hydrolysis takes place by nucleophilic attack and progresses slowly, while silicate monomers start condensing before being fully hydrolyzed. Base-catalyzed products generally shrink less than those synthesized under acidic conditions, thus being lower density products.

The hydrolysis is followed by water and/or alcohol forming condensation reactions (Figure 2). Hydrolysis and condensation occur simultaneously rather than sequentially; in fact, Si–O–Si (siloxane) bonds have been observed immediately after the addition of water and catalyst to the alkoxide solution, suggesting that condensation is initiated as soon as the first alkoxy group has been hydrolyzed. The initial condensation is quite fast, within minutes or less [6], although it slows down as

Figure 1 Range of products that can be prepared via sol-gel processing.

Figure 2 Alkoxide sol-gel reactions: hydrolysis; water- and alcohol-forming condensation.

polymerization progresses. For $\text{Si}(\text{OC}_2\text{H}_5)_4$, tetraethyl orthosilicate (TEOS), the most popular silica precursor, the time for hydrolysis completion is less than 10% of the time for gelation under acid-catalyzed conditions.

The pH plays a critical role in all processes. Particularly at values lower than 3, complete hydrolysis, whereby four moles of water are consumed per mole of TEOS, produces linear or highly branched polymeric species that have a fractal structure and nanopore diameters lower than 2 nm. As the pH increases toward 7, dissolution and condensation reactions become relevant, promoting Ostwald ripening or coalescence and enhancing the coarsening of the structure. Above pH 7, the growth rate of particles is maximum because an increasing silica solubility promotes depolymerization of siloxane bonds. In turn, the monomeric silica produced helps the aging process through an Ostwald ripening-coarsening mechanism that yields mesopore diameters of well above 2 nm.

For the synthesis of multicomponent gels, the polymeric solution route offers great possibilities. The miscibility of different alkoxide compounds allows in principle complete polymerization of all metal species to be achieved and, thus, highly homogeneous products to be synthesized. This principle notwithstanding, the distinct rates of metal alkoxide hydrolysis may cause heterogeneities and phase separation in the final gel. If two different metal-alkoxide precursors are used, however, a sequential addition process, by which the least-reactive alkoxide is pre-hydrolyzed to some extent before the more reactive is added, tends to prevent heterogeneities from appearing. In this way the two metal species can be placed randomly along the polymer chain. As an example, the

flowchart for SiO-TiO_2 synthesis is shown in Figure 3 where Ti isopropoxide (TIPOT) is the source of titania, the catalyst is acetic acid and ethanol (EtOH) the solvent; the composition of these products can vary all the way from pure silica to pure titania. Ultra low-expansion glass, a registered trademark of Corning Inc. (ULE[®]), is one such example. Displaying a very low coefficient of thermal expansion of about 10^{-8} K^{-1} between 5 and 35 °C, ULE is composed of silica and less than 10 % titania. Sol-gel zirconia powders are another example of how solid-state allotropic phase transitions may be suppressed by a colloidal chemistry approach.

In sol-gel film deposition, the most common methods used to ensure fast drying of the solvent are dip- and spin-coating (Figure 4). With the former, a substrate plate is immersed in the sol and slowly withdrawn at a constant rate of the order of $\sim 1\text{--}30 \text{ cm/min}$, while drying at the meniscus leads to the progressive deposition of a thin film on the substrate; the faster the withdrawal, the thicker the film obtained, which can reach several microns. This method is especially suitable for coatings on large surface areas, for example, on glass windows. In the spin-coating process, the sol is dispensed on top of a horizontal substrate, which is then rotated at high speeds of the order of 1500–3000 rpm, for short times of $\sim$ about 20–30 seconds. Spin-coating allows the deposition of films on one side only of substrates of surface areas of up to $\sim 1 \text{ m}^2$. A high-quality thin film is deposited through quick elimination of the excess liquid by fast evaporation. The electrodeposition (or electrophoretic deposition) method is also used, for example, to coat metallic substrates, but less frequently. Depending on their charge, the particles (in a sol) or the polymers (in a solution) move in a direction opposite or parallel to an applied external electric field and then are deposited on the piece to be coated, which serves either as the cathode or the anode.

A variety of substrate geometries may be accommodated. After the gel film is dried, it can be sintered at a temperature near T_g into a dense glass. Depending on the actual deposition method used and on the viscosity of the precursor sol, the thickness of a single layer of inorganic films may vary from a few tens up to $\sim 300\text{--}400 \text{ nm}$. If thicker layers are sought after, multilayered films may also be prepared, several microns thick, through a sequence of dip- or spin-coating and rapid intermediate thermal annealing steps. Additional possibilities also arise if the substrate has previously been micro-patterned because a multitude of structures with different shapes and architectures can be fabricated, thanks to the wide range of designs offered by soft lithography. As a matter of fact, coatings are immune of the bubbles and carbon particles that result from incomplete hydrolysis and are usually difficult to eliminate in monolithic products. Because processing is much easier for coatings than for

Figure 3 Flowchart of the silica-titania sol-gel process, with $\text{pH} \leq 2$.

Figure 4 Sol-gel film deposition methods: (a) spin-coating and (b) dip-coating.

monoliths, about 10 m^2 of flat defect-free glass films have already been produced.

2.3 Hybrid and Other Sol-Gel Materials

Incomplete structural relaxation during drying is a central problem when it comes to produce monoliths or thick films. If the stress caused by capillary forces within the gel pores exceeds a certain critical value, cracks will appear either during drying, especially in monoliths, or during the final densification in thick films. Several approaches have been proposed to overcome this inherent weakness. In the late 1970s, organic groups such as $-\text{CH}_3$, $-\text{C}_2\text{H}_5$, and $-\text{C}_{11}\text{H}_{24}\text{O}_4$ began to be incorporated into the gel network within which bonding was made possible by the non-hydrolyzable $\text{Si}-\text{C}$ bonds of the precursors. This procedure gave rise to the so-called ORganically MODified SILica materials, known as ORMOSILS [7], which belong to the general category of hybrid (organic/inorganic) materials. The presence of the more compliant organic groups, together with the eventual cross-linking between hybrid polymeric chains, allows mechanical properties to be tailored and stress to be dissipated by plastic deformation.

For example, ORMOSIL materials combine the mechanical strength, chemical resistance, thermal stability, and optical transparency of glasses and ceramics with the toughness, flexibility, and lightweightness of organic polymers. Further, network porosity and surface chemistry can be tailored to the designed performance. These materials have even a higher versatility than silica: the presence of organic groups not only makes them more flexible but it also allows wettability to be adjusted by a judicious choice of the ratio of hydrophilic ($\equiv\text{Si}-\text{OH}$, $\equiv\text{Si}-\text{O}-\text{Si}\equiv$) to hydrophobic ($\equiv\text{Si}-\text{R}$) groups. The hybrid materials are usually processed at the fairly low temperatures of about 200°C at most for a couple of hours, in order to preserve the organic species, so they are ideal for coating plastic substrates.

Supercritical drying is another possible method to avoid gel shrinkage. Here, the liquid is removed through drying above its critical point so that no capillary stresses develop since no liquid-vapor interface exists. The resulting gel, named *aerogel*, has a volume similar to that of the dried wet gel, with a huge residual porosity (Chapter 8.3). This causes the aerogel materials to be, for example, extremely good thermal and sound insulators.

Sol-gel materials with a tailored porosity are other interesting products. After the seminal work conducted

in the early 1990s by researchers at the Mobil Oil Corporation [8], surfactants such as Brij56™, C16TAB, or C12TAB (lyotropic liquid crystalline phases) have been used as templates for sol-gel materials. One of the advantages of using homogenous phases as templates is that the nano-architecture of the reaction mixture is retained throughout the condensation and gelation processes so that the nanostructure of the material can be determined *a priori*. Thin films of nanostructured mesoporous silica, for example, are of interest for a range of applications, in particular for medicine and integrated sensors.

3 Advantages and Drawbacks of the Sol-Gel Process

The sol-gel process has many advantages over conventional melting-quenching techniques, especially in terms of improved purity and lower fabrication temperatures. However, difficulties related to the production of large, dense monoliths and to the cost of the starting materials still persist. These advantages and drawbacks over the classical melting-quenching technique are thus summarized in Tables 1 and 2.

4 Sol-Gel Products and Applications

The dimensionality of current types of products ranges from 0 (nanoparticles), to 1 (fibers), 2 (coatings), and 3 (bulk glassy materials). In this chapter, we will restrict ourselves to products and applications where glass is involved as the sol-gel material, or, at least, as the substrate.

4.1 Nanoparticles

Inorganic and hybrid sol-gel micro- and nanoparticles (Figure 5) have attracted much attention in recent years within both the academic and industrial communities. In addition to their huge surface-to-volume ratio, favoring miniaturization, nanoparticles give rise to unique optical, electronic, and magnetic properties, depending on their size, shape, and composition.

Nanoparticles may exhibit a wide range of geometries – from spherical to tubular, through centric, eccentric, and star like – may be plain or nanostructured – core-shell or porous structured – have different sizes and shell thicknesses, be hollow, differ in crystallinity and surface morphology, and finally be fine-tuned relative to one or more properties. Furthermore, they can be functionalized in

Table 1 Advantages of the sol-gel process.

Advantages	Comments
1. Formation of homogeneous noncrystalline solids in original composition ranges	One of the main advantages of SG processing lies in the possibility of preparing new glass compositions that would otherwise undergo liquid-liquid unmixing or crystallize upon quenching of a high-temperature melt.
2. Formation of new metastable crystalline solids with unusual compositions	Possibility of precipitating crystals that do not form at higher temperatures because of either slower kinetics or greater metastability than other crystalline forms or assemblages.
3. Special products, such as nanoparticles, films, and fibers	For films, possibility of low-temperature coatings not affecting the stability of the substrate. Dense, hollow, or core-shell nanoparticles, either inorganic or hybrid, may be obtained.
4. Improved homogeneity	Multicomponent oxides with a well-defined stoichiometry, or doped, may be prepared from different chemical precursors, even if the SG kinetics of the different precursors must be carefully controlled to produce the designed multicomponent composition with the required level of homogeneity. Mixing of the precursor solutions at the molecular level ensures an extra degree of homogeneity.
5. Improved purity	Another significant advantage lies in the outstandingly high purity of the final products. The use of liquid precursors containing less than 100 ppb of total metals, such as orthosilicates, together with solution handling at room temperature without any contamination from the container, guarantees the very high purity of typical SG products.
6. Low-temperature preparation	Owing to their high surface energies, colloidal particle compacts sinter well below their thermodynamic melting temperatures, whose actual values depend on the particle size, shape, or composition, or near the T_g of their melt-quenched glass counterparts. Low sintering temperatures not only mean lower energy costs but also contribute to the purity of the final product, which is free of contamination from refractory-lined furnaces. This is particularly important for silica glass, which needs to be melted well above 2000 °C.

Table 2 Drawbacks of the sol-gel process.

Disadvantages	Comments
1. Raw materials costs	Most precursors have a relatively high cost, despite a continuing decreasing trend, such that the SG process is more suitable for specialty glass products, where raw materials' cost is not critical, than for large-scale production. For example, the raw materials' costs for 1 ton of sol-gel silica are ~47 000€, against ~200€ when produced by traditional melt/quenching of high-purity silica sand. It is therefore unlikely that high-volume glass products like flat glass, container glass, cooking ware, and common fibers will be produced by the SG technology.
2. Large shrinkage during processing	SG products have a high pore volume where solvents and eventual excess reagents may be trapped. The complete removal of the liquid phase and elimination of porosity during drying and sintering causes a significant degree of shrinkage of the final SG product compared to the initial wet gel, particularly for monoliths and thick films, which complicates near-net shape design.
3. Residual hydroxyl groups and carbon	Hydroxyl and carbon residues (the latter mostly in monoliths) are difficult to eliminate completely.
4. Health hazards of organic solutions	Continuous or isolated exposure to organic solvents may cause: I. Acute poisoning Narcosis; irritation of throat, eyes, or skin II. Chronic poisoning Liver and kidney damage; blood damage; nervous system damage Alcohols in particular, besides being anesthetics, may cause irritation of the eyes and upper respiratory tract.
5. Long processing times	This is a problem with monolith fabrication, but not with thin films. The deposition of thick multilayer films is more time-consuming.
6. Difficulty in producing large pieces	Again this concerns monoliths; the deposition of large area coatings usually presents no problem.

Figure 5 Transmission electron microscopy images of sol-gel silica nanoparticles: (a) inorganic dense NPs, (b) ORMOSIL dense NPs, (c) inorganic nanostructured NPs (templated with Brij₅₆), and (d) inorganic hollow-nanosphere (dark circle in the figure).

situ and further conjugated with a wide range of small ligands (usually organic) and/or large biomolecules. This connection with biomolecules through bonding of a protein, a peptide, an antibody, or other molecules makes possible to target a nanoparticle to specific sites in the organism, in particular to specific cellular receptors [9].

Additionally, nanoparticles enable the encapsulation and controlled release of various substances (e.g. drugs, biomolecules, cosmetics, dyes, and inks) and may enhance a catalytic action. Its high photocatalytic efficiency, thermodynamic stability, and low cost make titanium dioxide (TiO_2) the prime candidate for photocatalytic use at an industrial scale [10]. Such TiO_2 nanoparticles may, for instance, decompose pollutants by reactions (either oxidation or reduction) photocatalyzed at their surface. The different forms of active oxygen produced – O_2^- , $\cdot\text{OH}$, $\text{HO}\cdot$, and $\text{O}\cdot$ – cause polluting agents, either organic or inorganic to break down according to the following reactions [11]:

where e^- designates an electron, h^+ a photon, and (ad) indicates an adsorbed species.

Another advantage is that the nanoparticles can be nanostructured in situ through the use of surfactant templates or may even be made hollow [12, 13] (Figure 5c and d, respectively). Finally, nanoparticles can be multifunctional, i.e. be capable of accomplishing multiple objectives such as serving for imaging and delivering drugs (*theranostics*), or performing a single advanced function through incorporation of multiple functional units. For biomedical applications, an appropriate size range (~10–200 nm) and a mono-sized distribution are normally required for effective operation. Inorganic or hybrid sol-gel coatings can also be combined with a wide range of core materials in core-shell nanostructures.

As exemplified by SiO_2 nanoparticles, the classical aqueous route comprises two main alternatives: the microemulsion process (or reverse microemulsion) and Stöber method. In the first case, a reverse-micelle or water-in-oil microemulsion system is formed by mixing water, oil, and surfactant. The reactions take place in the dispersed aqueous phase, forming confined reaction vessels. The nucleation and growth kinetics of silica nanoparticles are highly conditioned by the size of water droplets in the microemulsion system, while the surfactant coating prevents agglomeration and enhances the nanoparticle colloidal stability. Dynamic adsorption and desorption of surfactant molecules at the nanoparticle

surfaces during growth, particularly the selective adsorption toward crystal faces, enables one to control the nanoparticle size, size distribution, and morphology. In the procedure described by Stöber et al. [14], SiO_2 nanoparticles are produced by hydrolysis of an alkoxide precursor such as TEOS in an ethanol solution, under basic catalysis. This hydrolysis starts producing silicic acid, which condenses to form highly porous amorphous nanoparticles. The Stöber method is a room-temperature, surfactant-free route that ensures an eco-friendly synthesis of nano- or microparticles, with diameters comprised between 30 nm and 2 μm [15].

Aqueous sol-gel chemistry may nonetheless be complex when it comes to nanoparticle synthesis. The difference in reactivity of the metal oxide precursors, the competition between hydrolysis and condensation reactions, and possible aggregation or Ostwald ripening may prevent the nanoparticle size, size distribution, and morphology from being controlled. Additionally, the as-synthesized oxide nanoparticles are often amorphous and the final crystallization process may harm process reproducibility. Although much less popular, another chemical route to produce oxide nanoparticles is nonaqueous. Here, no water is present, the oxygen being provided by solvents such as ethers, alcohols, ketones, or aldehydes, or by the organic constituents of the alkoxide or acetylacetone precursors [16].

4.2 Coatings and Thin Films

Whereas fibers are still not very common, coatings and thin films are, by far, the most important category of products and applications at present ([17], Chapter 6.8). Many of these coatings exhibit several functional properties obtained via easy and fast processing. Those considered here may be glassy films on a glass or another type of substrate, or at least partially crystalline films, but deposited on glass substrates. For such products and applications, either inorganic or hybrid materials are utilized, the latter having the advantage of low-temperature post-processing by UV irradiation or heat treatment made online after a deposition step often made with standard industrial technologies. The main categories may be divided into the following six applications: (i) automotive, (ii) architectural, (iii) ophthalmic, (iv) electronic, (v) household, and (vi) optical.

In the category of automotive coatings, head-up displays are becoming common in some cars in the high-end of the market. Based on silica-titania films, they allow drivers to read information on the rear-view mirror or on the inside surface of the windshield without having to watch off the road (Chapter 9.2). Besides, water-repellent (hydrophobic) and abrasion-resistant transparent coatings for automotive windows may, for example, be micro

phase-separated silica-titania films (from silica precursors like MTES, methyltriethoxysilane). There are also colored coatings for tinted automobile windows as well, based on different transition metal oxides dispersed into silica films.

Architectural products (Chapter 9.1), on the other hand, include solar-control coatings reflecting both the near ultraviolet and near-infrared components of the solar spectrum, self-cleaning (photocatalytic) titania coatings for glass windows, or electrochromic coatings for glass windows in buildings, which change color by means of an applied electric field. Besides, dichroic windows for building display beautiful variable colors because they display interference effects from alternating multilayer stacks of high/low refractive index materials like titania ($n \sim 2.2$) and silica ($n \sim 1.46$).

Similar applications are found for ophthalmic products. Antireflection and (hard) anti-scratch hybrid coatings cured at low temperatures are, for instance, used for plastic eye lenses. The former may be optical thin films of low refractive index ($n < 1.30$). These are, for example, obtained with an MgF_2 - SiO_2 mixture where the presence of the light element F lowers the density, and thus the index of refraction.

In the area of electronics, antireflection coatings are extensively used. Transparent conducting oxide coatings like ITO (Indium-Tin-Oxide, $\text{In}_2\text{O}_3 : \text{Sn}$), or ATO (Antimony-Tin-Oxide, $\text{SnO}_2 : \text{Sb}$), serve as electrodes for various applications such as solar cells, display glasses, sensors, and electrochromic windows (Chapter 6.10). Other transparent conducting oxide coatings are deposited in glass tubes for antistatic properties, for example, in flow meters. Mention should also be made of the “spin-on glass,” which designates a silica-based sol for

the planarization of electronic integrated circuits and has become an important product available worldwide.

Examples of household applications are the antifogging hydrophilic coatings, based on SiO_2 - ZrO_2 layers deposited on glass windows and mirrors, for example, in bathrooms, where the introduction of zirconia decreases the wettability of the silica films.

Coatings for optical devices include antireflection coatings of high-performance lenses with the aforementioned MgF_2 - SiO_2 mixture. Likewise, such coatings with a high laser damage threshold are made up of porous silica films for potassium dideuterium phosphate crystals in frequency-doubled lasers, as well as for glassy optical waveguides and waveguide sensors (such as biosensors).

Another interesting application concerns sol-gel-derived photonic crystal coatings like Bragg mirrors for solar control (already mentioned as an architectural product), Fabry-Perot microcavities for white-light generation applications [18], and opal/inverse opal coatings for strain sensors [19], of which two examples are shown in Figure 6. Like dichroic windows, Bragg mirrors consist of alternating multilayer stacks of high/low index materials but in their microcavities the mirror periodicity is interrupted by a double thickness defect layer, which may be doped for white light generation with active elements such as lanthanides. The synthetic opals and inverse opals are derived from self-assembled close-packed arrangements of dielectric spheres. Another category of coatings that do not belong to the previous ones are the wide variety of inorganic and hybrid films, for example, made up of ZrO_2 -, TiO_2 -, Al_2O_3 -, or CeO_2 -bearing silicates, which are used for protecting metals such as steel.

Figure 6 Examples of sol-gel prepared photonic crystals: (a) Fabry-Perot microcavity of alternating high/low index films for white light generation; (b) titania inverse opal for sensing. (Both (a) and (b) are scanning electron micrographs).

4.3 Bulk Sol-Gel Products

Bulk sol-gel products include the cladding tube of fiberoptic preforms (Chapter 6.4), essentially made of base-catalyzed silica, gradient index rods based on Ti leaching from (SiO_2 -rich) silica-titania glass rods, or membranes with tailored porosity for separation and filtration or other applications. Of interest are also high-performance-liquid-chromatography (HPLC) column fillings based on porous silica monoliths with a bimodal meso/macroporous ($\sim 0.1\text{--}40\text{ }\mu\text{m}$) pore size distribution. They are prepared by hydrolysis and polycondensation of alkoxy silanes in the presence of water-soluble polymers, which leads to polymer-induced phase separation [20]. Another interesting application of the concept of bimodal pore size materials is nano/macroporous scaffolds for bone tissue regeneration ([21], Chapter 8.4), such as calcium phosphosilicate glasses shown (Figure 7). Sol-gel glasses have also been suggested as a possible matrix for nuclear waste encapsulation as an alternative to borosilicate glasses (Chapter 7.6) because of the advantage of low-temperature sintering compared to high-temperature melting and also of the possibility of incorporating a wider range of radioactive elements. Finally aerogels, thanks to the extremely large porosity associated with a density of $\sim 0.1\text{ g/cm}^3$ for a typical silica composition, have thermal conductivities lower than 0.02 W/mK and are thus used as highly efficient thermal insulation materials, as well as in sound insulation and Cherenkov (γ -ray) detectors. The upper temperature limit for use in thermal insulation is $\sim 1000\text{ }^\circ\text{C}$.

5 Perspectives

The sol-gel technology is a field that has been expanding at a very significant rate. However, the fact that its applications are largely dominated by coatings means that the material produced is often only a component integrated within a larger product whose fabrication may involve several other technologies. For the electronic industry, spin-on-glass films with different functionalities are a good example of this paradigm, which may ultimately affect the visibility of many sol-gel products. One of the most attractive features of the sol-gel process is that it may produce materials with compositions that cannot be obtained with conventional methods. One can thus expect quite new glasses to be created in the future, even if only as thin films, thanks in particular to the continuous development of less expensive precursors and more stable sols. On the processing side, more reproducible preparation conditions will be implemented in terms of temperature and humidity control. Concerning coating technologies, it is likely that there will be an increasing use of spray- and roller-coating methods for large area depositions, as well as of ink-jet printing, which has the additional advantage of being applicable to 3-D additive manufacturing. Since the electronics and biomedical applications appear to be the fastest growing segments, one may actually expect increasing examples of 3-D printing of different objects. Bioactive glass scaffolds with tailored porosity for tissue engineering is one outstanding example of such innovative developments (Chapter 8.4).

8.3

Silica Aerogels

Wim J. Malfait, Jannis Wernery, Shanyu Zhao, Samuel Brunner, and Matthias M. Koebel

Laboratory for Building Energy Materials and Components, Empa, Dübendorf, Switzerland

1 Introduction

As indicated by their name, aerogels are highly porous materials prepared from gels (Chapter 8.2). Even though their solid skeleton can be prepared from inorganic crystalline materials or (bio)polymers with various degrees of crystallinity [1, 2], aerogels made up from amorphous silica are by far the best-studied and also the most relevant industrially, thanks to their outstanding or even record-breaking properties (Table 1). Such features as their unique translucency (Figure 1), high surface area, lowest ambient-pressure thermal conductivity known to man, and low to ultralow density are due to the mesoporous structure (2–50 nm pore diameter) rather than to the amorphous nature of the silica that builds up an open, porous three-dimensional network of linked nanoparticles around the pores. This is why the solid phase in aerogels is not a priori required to be glassy and why other substances can alternatively be used to obtain material properties approaching those of silica aerogels.

When one starts from a condensed gel phase, the basic problem faced to form an aerogel is to eliminate the solvent without causing at the same time a structural collapse of the residual phase through capillary forces. Samuel Kistler solved this problem through supercritical alcohol drying at elevated pressure and temperature when he synthesized the first silica aerogels in the 1930s [3, 4] at the College of the Pacific, California and Stanford University. His work was motivated by basic scientific interest into the structure of gels, but the

resulting aerogels were subsequently produced industrially by Monsanto Chemicals between 1940 and 1960 as thermal insulators and viscosity regulators. Even though the initial discovery of aerogels was made at a university, most of the early development took place in industrial rather than academic settings and much of it is not publicly available. The high citation rate of *silica aerogel* in patent applications, which outnumbers that in the scientific literature between 1930 and 1995 (Figure 2), reflects the importance of these industrial developments.

Together with an industrial revival, academic interest in aerogels took off around 1990. Since then the number of publications has strongly increased and kept track with the number of patents. The renewed interest resulted in major technological breakthroughs (Chapter 8.2) such as the use of alkoxide precursors that circumvent the cumbersome ion exchange needed for waterglass precursors [5]; the advent of supercritical CO₂ drying, which occurs at much lower temperatures compared with supercritical alcohol drying [6, 7]; and the feasibility of ambient-pressure drying which obviates the need for high-pressure equipment altogether [8].

In this chapter, the synthesis and then the particular properties of aerogels will be first described. The manner in which applications rely on these properties will then be presented.

Industrially, these advances have culminated in the production ramp-up of silica aerogel for blankets (Aspen Aerogels) and granulates (Cabot Corporation). As will be also discussed, since then various other manufacturers have entered the market. Finally, attention will be paid to research done in Academia where much of the research focus has been on the characterization of silica-aerogel microstructure and on the development of new metal, metal oxide, polymer, and polymer-silica hybrid aerogels.

2 Synthesis

2.1 Sol–Gel Chemistry

Silica aerogels are produced through sol–gel synthesis (Chapter 8.2), optional surface modification (hydrophobization), and removal of the solvent (Figure 3). There are two common silica sources, namely, waterglass (Chapter 7.5) and alkoxides (Chapter 8.2). Molecular silicate species and small clusters in ion-exchanged waterglass rapidly aggregate at low pH into silica nanoparticles 2–5 nm in diameter. In academic research, however, the most commonly used precursors are silicon

alkoxides such as tetraethoxysilane [Si(OC₂H₅)₄, TEOS] and tetramethoxysilane [Si(OCH₃)₄, TMOS], which are typically gelled by a two-step acid–base catalyzed sol–gel process [9]. The silica sol is generated from the alkoxides by addition of a solvent (most commonly ethanol or methanol), water, and an acid catalyst. A series of hydrolysis and condensation reactions then takes place, resulting in the formation of SiO₂ nanoparticles along with additional parent alcohol. Regardless of the waterglass or alkoxides silica source, gelation of these slightly acidified sols can be triggered by the addition of a base or additional acid, causing formation of the three-dimensional network of these silica nanoparticles.

Figure 3 Sol–gel synthesis of a surface-modified aerogel.

2.2 Aging and Surface Modification

One can improve the mechanical stability of gels by an aging process whereby, as driven by surface-area minimization, dissolution–reprecipitation reactions akin to Ostwald ripening reinforce the weak interparticle necks. Aging is particularly important for silica gels that will be dried at ambient pressure (i.e. in an oven by simple evaporation) as it enables the gels to withstand the strong capillary forces that occur during the process.

Without a hydrophobization treatment, silica surfaces are covered with silanol groups [$\equiv\text{Si}-\text{OH}$], which makes them inherently hydrophilic: both liquid water and water vapor readily penetrate the aerogel mesopores and cause irreversible shrinkage and pore collapse. Therefore, nearly all commercially available silica aerogels have undergone a surface modification whereby hydrophobic groups, typically trimethylsilyl [$-\text{OSi}(\text{CH}_3)_3$], substitute for hydroxyl or ethoxy groups on the silica surface [10]. This hydrophobization treatment results in water contact angles higher than 140° , prevents water from penetrating into the aerogel's mesopores, strongly limits the humidity uptake, and promotes the so-called spring-back effect during air-pressure drying and under mechanical loading.

2.3 Supercritical Fluid Versus Ambient-Pressure Drying

As already noted, the production of an aerogel inevitably involves a drying step in which the gelation or modification solvent is removed. However, very strong capillary forces act on the aerogel particle network upon evaporative drying because of the small diameters of the pores. They result in condensation reactions between adjacent surface silanol groups that irreversibly cause a strong shrinkage for non-hydrophobized aerogels upon ambient-pressure drying. The resulting materials are relatively dense xerogels with porosities on the order of 50%, rather than the values larger than 90% of aerogels. For the first materials, supercritical alcohol-drying at pressures and temperatures of at least 50–100 bars and 200–400 °C, respectively, had to be used by Kistler to eliminate capillary forces and prevent pore collapse. The advent of supercritical CO_2 drying [6, 7] enabled a drastic reduction in drying temperature down to 40 °C (at 80–100 bar) so that it is now the preferred drying method for most types

of aerogels. Supercritical CO_2 drying is a commercially viable process, but it inevitably involves batch-type processes that require high-pressure autoclaves and add cost and complexity to the production process. Many aerogel-producing companies have therefore adopted the ambient-pressure drying process proposed by Prakash et al. [8], where the hydrophobization of the silica surfaces is followed by conventional, often continuous, evaporative drying. With this methodology, capillary forces are not avoided, but the hydrophobized apolar surface minimizes the interaction between the particles, resulting in a spring-back effect and recovery of up to 95% of the original porosity of a sufficiently aged gel.

3 Properties

3.1 Microstructure and Porosity

Some of the silica-aerogel benefits are due to the glassy nature of the silica particles themselves; for instance, the distinct nanotoxicity advantages compared to materials made from non-biosoluble crystalline silica and silicates [11, 12]. However, most of the unique properties of silica aerogels, and ultimately their applications, critically depend on their microstructure. At the smallest length scales, these aerogels display a “pearl-necklace” structure of silica particles joined together by thin interparticle necks (Figure 4a). The primary silica particles are typically between 3 and 5 nm in diameter and require transmission electron microscopy (TEM) to be observed. They form larger secondary particles typically 20–50 nm in diameter whose ensemble can be more readily observed by scanning electron microscopy (SEM, Figure 4b). The electron-microscopy micrographs clearly point to a highly porous, predominantly mesoporous (2–50 nm) microstructure. Whereas TEM and SEM provide a direct view into the microstructure, statistically more relevant structural information can be obtained from nitrogen sorption (BET), mercury intrusion, and small-angle X-ray and neutron scattering experiments (SAXS and SANS). These measurements confirm the predominantly mesoporous nature of silica aerogels. The scattering experiments, in particular, provide strong evidence for the fractal nature of these materials with typical fractal dimensions around 2.4–2.7 [13]. The small

Figure 4 Microstructure of a typical silica aerogel. (a) Pearl-necklace structure highlighted by transmission electron microscopy. (b) Larger secondary particles (20–50 nm) enclosing the mesopores in a scanning electron microscopy micrograph.

diameter of the primary particles leads to large surface areas in the 500–1000 m²/g range.

3.2 Silica and Surface Chemistry

Silica gels prepared without a hydrophobization treatment (and their supercritically dried aerogel analogues) contain a substantial fraction of non-bridging oxygen atoms because of the presence of abundant silanol and/or alkoxide groups ($\equiv\text{Si}-\text{OR}$ where $\text{R}=\text{H}$, CH_3 , C_2H_5). The particle surface thus contains a large fraction of Q^3 species, with minor fractions of Q^2 , in contrast to the particle cores that consist mostly of Q^4 [10], where a Q^n species is a Si atom coordinated by n bridging and $4-n$ non-bridging oxygen atoms (Chapter 2.4). As emphasized above, nearly all commercial silica aerogels have undergone a surface modification treatment to render them hydrophobic and to enable ambient-pressure drying. During hydrophobization, a large fraction of the silanol and (m)ethoxy groups are replaced by trimethylsilyl groups. Depending on the silica precursor and processing steps, the result is a surface coverage with trimethylsilyl, silanol, and (m)ethoxy groups in various proportions. Spectroscopic tools to characterize the surface chemistry are available in the form of Fourier transform infrared (FTIR) (qualitative) and solid-state nuclear magnetic resonance (NMR) spectroscopy (quantitative) (Figure 5). The concentrations and surface coverages of the various functional groups are now well known for a range of archetypal silica-aerogel materials, with typically about three to four trimethylsilyl and one ethoxy/silanol group per nm² of surface area for well-hydrophobized silica aerogels [10].

3.3 Thermal Conductivity

Typical insulation products are highly porous materials in which heat is conducted by means of three major

Figure 5 Surface chemistry of a TEOS-based silica aerogel. (a) As probed by Fourier transform infrared spectroscopy. (b and c) By solid-state NMR spectroscopy; peak areas directly giving the relative abundances of the various species.

mechanisms: conduction through the solid skeleton, conduction through the gas inside the pores, and radiation. Of these three, the gas-phase conduction usually dominates. The thermal conductivity of silica aerogels can

Figure 6 Minimum in the thermal conductivity of aerogels at intermediate densities as illustrated by data for silica aerogels [14].

be as low as 12–18 mW/(m·K) (Figure 6) which is half that of standing air, i.e. 26 mW/(m·K), even though aerogels feature air-filled pores. This low thermal conductivity originates in the mesoporous structure of silica aerogels where most pores are smaller than the mean free path of O_2 and N_2 molecules in air, namely, about 70 nm under ambient conditions. These molecules thus have a higher probability to collide, and thus to transfer kinetic energy, with the pore walls than with other molecules. The heat transfer within the gas phase is reduced, a feature known as the Knudsen effect, and the heat transfer from the pore wall to the gas phase is inherently inefficient.

The solid-phase conduction through the silica particles is also low, thanks to the high porosity of the material, the nanoscopic and thus ultrafine network structure with thin interparticle necks (Figure 4a) and the relatively low thermal conductivity of bulk silica glass of 800–1000 mW/(m·K) at room temperature. Whereas radiative contributions are rather limited at room temperature, infrared opacifiers such as carbon black or titania [TiO_2] are common additives for high-temperature applications for which blackbody radiation would otherwise propagate almost freely through the translucent material.

As commonly observed for insulating materials, aerogels display a minimum in thermal conductivity at intermediate densities (Figure 6), commonly around 0.1 g/cm^3 [1]: at even lower densities, the average pore size approaches the mean free path of air molecules, which causes an increase in gas conduction and radiative transport whereas solid conduction

through the silica skeleton begins to dominate at higher densities [14].

3.4 Mechanical Properties

The often cited high strength-to-weight ratio of silica aerogels is somewhat deceptive as it is more due to low density rather than to outstanding mechanical properties. In fact, the properties of silica aerogels depend very strongly on the density of the material (Figure 7), with brittle behavior for high densities ($\rho > 0.2 \text{ g/cm}^3$), elastic behavior at intermediate densities ($0.2 > \rho > 0.1 \text{ g/cm}^3$), and highly compressible, ductile behavior at low densities ($\rho < 0.1 \text{ g/cm}^3$) [14]. Low-density aerogels can accommodate very large strains but have a Young modulus as low as 0.1 MPa for $\rho \sim 0.050 \text{ g/cm}^3$, whereas high-density aerogels have a high Young modulus of nearly 70 MPa for $\rho \sim 0.350 \text{ g/cm}^3$ but are brittle like glass and fail even at strains lower than 20%.

It should be noted that mechanical data are generally collected under controlled conditions on crack-free laboratory specimens. For real-world applications, the presence of internal cracks and other defects typically results in drastically reduced performance and brittle fracture (Chapter 3.11). As a consequence, silica aerogel applications usually make use of aerogel blankets where individual grains are kept in place by fibers or other products where the aerogel granulate is combined with a binder or placed inside specific cavities. As described in 6, there is thus significant ongoing research on the mechanical reinforcement of silica aerogels at the microscopic structural level such as through addition of various polymers during or after gelation.

Figure 7 Density-dependent uniaxial compression curves for silica aerogels [14].

4 Applications

4.1 Thermal Insulation

By far the best-established application of silica aerogels is as thermal superinsulators [15, 16]. The unique selling point of silica aerogel is an ultralow thermal conductivity, but additional advantages are a relatively low flammability, a vapor open structure, and hydrophobicity. The low thermal conductivity enables one to use thinner insulation to reach the same thermal performance as with conventional materials. This advantage is offset by the high cost of silica aerogel products, which is up to 20 times higher than that of mineral wool. As a result, most applications are in niche markets where either space for thicker insulation is not available or where space savings result in large cost savings.

The former case is that of the building sector for which aerogels have given rise to a wide range of technical solutions: boards, translucent elements, blankets, or renders and concrete (Figure 8). These are particularly valuable for building retrofit where the use of thick layers of conventional insulation materials is often impossible for technical or aesthetical reasons, in particular in buildings under heritage protection. Likewise, silica-aerogel insulation is beginning to find its way into new buildings, particularly in areas with high property prices (e.g. inner city centers) where the gain in usable floor space offsets the added cost of an aerogel solution. In addition, these products are often used to eliminate thermal bridges at specific locations in a façade.

Currently, however, the largest silica-aerogel market is industrial insulation. Blankets are particularly common materials for pipe insulation (Figure 8e), including oil-and-gas pipelines for which space savings translate into very large cost savings during transport and installation. In addition, silica aerogel is mechanically and chemically stable up to at least 300 °C and the permanent hydrophobic nature of such products eliminates liquid (sea)water intrusion and thus positively affects the corrosion resistance of steel pipe assemblies.

4.2 Alternative Applications

The unique properties of silica aerogels have also given rise to non-insulating applications, albeit at much smaller production volumes. Of note are space applications, which have driven substantial research and development on both silica- and polymer-based aerogels where NASA has been a key player. A low-density silica aerogel has, for instance, been used as a capture material for hypervelocity cosmic dust particles because its mesostructure ensures a sufficiently gentle dissipation of the particles' kinetic energy and allows their intact capture, whereas

its transparency enables an easy recovery of the impacted particles for the variety of chemical and physical analyses performed to understand better cosmochemical processes (Figure 8d) [17]. Other applications are based on silica aerogels' low refractive index for the detection of Čerenkov radiation [18] or exploit their large surface area and/or sorption capacity: additives for foundry applications [19], oil-spill clean-up materials [20], catalyst support materials [21], gas adsorption [22], and drug delivery [23].

5 Markets and Industrial Production

5.1 Markets

A recent Markets and Markets study estimates the 2014 global aerogel market at 200–300 MM US\$ with a compound annual growth rate of 19%, leading to a predicted 2019 aerogel market of over 500 MM US\$ [24]. Aspen Aerogels, the market leader in silica-aerogel products, fabricates a variety of hydrophobic, fiber-reinforced silica-aerogel blankets and reported a marked increase in its revenues of 63 (2012), 86 (2013), 102 (2014), and 122 (2015) M US\$, corresponding to an estimated ramp-up in production volumes from 20 000 to 50 000 m³ over this period. These numbers are in line with several existing market research studies, particularly with respect to the compound annual growth rates. Cabot Corporation, a global chemicals and materials manufacturer, probably is the second largest aerogel producer with a turnover of ~20 MM US\$ from a production of 5 000–10 000 m³ of silica-aerogel granulate per year. In addition to these well-established players, a great many new companies have recently entered the market, including Enersens, Guangdong Alison, and Nano High-Tech Co., which all produce a variety of silica-aerogel products (granulate, powders, boards, and blankets) and also JIOS Aerogel, which specializes in silica-aerogel powders. Even though the oil-and-gas segment accounts for about 75% of the current market, the fastest growth rates are expected from the construction and automotive/transportation sectors [24].

5.2 Production Technology

Two types of precursors (waterglass and alkoxides) and two drying technologies (supercritical CO₂ and ambient-pressure) are applied industrially for silica-aerogel production. Aspen Aerogels and most likely Guangdong Alison and Nano High-Tech Co. as well use silicon alkoxide precursors as the silica source and supercritical CO₂ drying to remove the pore fluid. In contrast, Cabot Corporation and JIOS Aerogel use waterglass

precursors and ambient-pressure drying for their respective granulate and powder production. Enersens combines alkoxide precursors with ambient-pressure drying. This variety of production technologies, combined with the high contributions of processing and overhead to the total production cost (compared to the starting materials), indicates that silica aerogel production has not reached full industrial maturity. This is in sharp contrast to established industries such as float glass (Chapter 1.4) or glass and mineral wool (Chapter 9.3) production.

6 Silica Hybrid Aerogels, Aerogel Composites, and Non-silica Aerogels

Common silica aerogels are rather brittle and their products can be quite dusty. As a result, significant academic and industrial research and development is devoted to the development of alternative aerogels with improved mechanical properties. Silica-like aerogels from methyltrimethoxysilane [$C_4H_{12}O_3Si$] precursors are highly flexible [25], but often display reduced surface areas and higher thermal conductivities. Bulk polymers and biopolymers are less brittle than inorganic glasses, which is also reflected in the corresponding aerogels. However, polymer and biopolymer aerogels typically suffer from a higher thermal conductivity and flammability. Therefore, much of the ongoing research on (bio)polymer aerogels aims at improving these properties [26]. An alternative approach aims at reinforcing silica aerogels through hybridization with various (bio)polymers [27, 28].

Most often, however, improvements in mechanical properties come at the cost of an increase in thermal conductivity. Some of these materials are nonetheless of industrial interest, thanks to a combination of a high strength-to-weight ratio with a moderately low thermal conductivity. Recently, an increase of the mechanical strength and a decreased dust release has been achieved through the addition of the biopolymer pectin prior to gelation, without a significant increase in thermal conductivity [29]. Alternatively, silica aerogels can be combined with stronger materials to build composites, for example, as aerogel embedded concrete [30] or by casting silica aerogel into honeycombs [31]. Although relatively far from the market, aerogels with unique properties have been prepared from a wide variety of materials such as metals, carbons, carbon nanotubes, graphene, titanium oxide, zirconia, etc., for battery, sorption cooling, solid oxide fuel cell, and catalysis applications [2].

7 Perspectives

The unique properties of silica aerogels, in particular their ultralow thermal conductivities, make them very attractive materials for a range of applications. Silica aerogels already constitute a rapidly growing niche market today, but a drastic reduction in production cost is required to enable them to penetrate the main insulation markets. Although suffering also from the price of the starting materials, the current high production costs are mostly related to the capital and operational expenses of a complex production process that involves lengthy and resource-intensive batch-type solvent exchanges (Figure 3) and, in the case of supercritical drying, expensive high-pressure equipment. However, continuous drying processes are under development and progress is also achieved toward a minimal solvent production process that would speed up the production process and limit the solvent consumption (1.2 m^3 of solvent for 1 m^3 of aerogel) to nearly the theoretical minimum of 1 m^2 of solvent for 1 m^3 of aerogel [32]. Such technological improvements, continuing innovation by the current market leaders, and the entry of new producers are signs of an overall maturation of the market that is expected to lead to a cost reduction of silica aerogels. This market maturation will lead to an expansion of the aerogel market beyond its current niches and with growth rates still higher than the current ones.

Bioactive Glasses

Delia S. Brauer¹ and Julian R. Jones²

¹ Otto Schott Institute of Materials Research, Friedrich Schiller University, Jena, Germany

² Department of Materials, Imperial College London, London, UK

1 Introduction

Glass is used in a wide variety of medical and dental applications, including chemically strengthened glass for epinephrine (adrenaline) autoinjectors (EpiPen®), silver-releasing glass for urinary catheters, glass fillers in dental composites, or glass-ceramic dental crowns. Bioactive glasses, by contrast, are designed to actively interact with the human body, release ions, and degrade over time [1].

Bone defects arising from disease (e.g. osteoporosis or tumor removal), trauma, or congenital defects, which are too large for the bone to heal itself, are usually treated with either allografts (i.e. donor bone) or autografts, which involve transplanting bone from another part, usually the pelvis, of the patient's body to the site of the defect. Both methods have disadvantages, however, among them being limited supply of bone and side effects such as pain at the donor site. Allografts, in addition, require careful screening to avoid the risk of transmitting diseases. Synthetic alternatives such as bioactive glasses can overcome these issues [2].

Bioactive glasses were developed by Larry Hench in the late 1960s [3], following a chance conversation with a colonel of the US army, who challenged him to produce a material that would not be rejected by the human body [4]. Knowing many soldiers who, following severe injuries during the Vietnam War, had their limbs amputated, the colonel realized that one reason was that the implant materials available at the time (bioinert metal and polymers) did not bond to body tissue but were rejected instead. Hench thus decided to experiment with a SiO₂-poor soda-lime silicate composition to which

P₂O₅ was added. His Bioglass 45S5, a phosphosilicate glass of the composition 46.1 SiO₂•2.6 P₂O₅•26.9 CaO•24.4 Na₂O (in mol %), turned out to be the first synthetic material to form an intimate bond with bone [5]. Before this discovery, implant materials were designed to be chemically inert to avoid any foreign body reaction in the human body. Bioactive glasses, by contrast, degrade in physiological solution, release ions, and form a surface layer of apatite. It is this combination of dissolution and apatite mineralization that makes bioactive glasses so successful at regenerating bone: bioactive glass granules implanted into a bone defect act as a three-dimensional (3-D) template to guide bone growth and help the bone to heal while they degrade.

Since the invention of the original bioactive glass, more compositions have been developed, many of them at Åbo Akademi in Turku, Finland. Among these are glasses S53P4 [6] and 13-93 [7], the latter being the first bioactive glass that could be processed at high temperatures without crystallizing. Further selected compositions are presented in Table 1. Two bioactive glasses, Bioglass 45S5 and S53P4 (BonAlive®), have approval by the US Food and Drug Administration (FDA) for a range of clinical applications [8]. They have now been used in more than a million patients and are gathering popularity among orthopedic surgeons.

In this chapter, we will describe two approaches for preparing bioactive glasses, namely, the high-temperature melt route and the sol-gel process. We will also look into their mechanism of interaction with body fluids before looking at current and possible future applications.

2 Melt-Derived Bioactive Glasses

Melt-derived bioactive phosphosilicate glasses consist of a silicate network of connected SiO₄ tetrahedra

1106	61.2	0.5	—	5.1	23.2	—	10.0	—	2.8	1.2

**Figure 1** Decreasing concentrations of modifier ions (spheres) and increasingly cross-linked silicate network (ball-and-stick models) for increasing silica contents as obtained from molecular dynamics simulations: Bioglass 45S5 (left) and glasses with 55 (center) and 65 mol % SiO₂ (right). Source: Reproduced from [9] with permission from the American Chemical Society.

(Chapter 2.1); however, in contrast to more chemically stable silicate glasses, bioactive glasses contain larger concentrations of modifier oxides, resulting in the presence of large numbers of nonbridging oxygens (Figure 1) and a lower network connectivity (a smaller average number of bridging oxygens per silicon atom; Table 1) [10]. Generally, bioactive glasses have a network connectivity between 2 and 2.6.

In addition, many bioactive silicate glasses contain small amounts of phosphate, usually up to 6 mol % P₂O₅. Although it was originally thought that SiO₂ and P₂O₅ form a mixed network containing Si—O—P bonds, it has now been recognized by solid-state ³¹P NMR results that most of the phosphorus is present as orthophosphate (PO₄³⁻) tetrahedra, charge-balanced by modifier cations [10]. Besides NMR spectroscopy and MD simulation, results have also shown the presence of phosphate clusters in these glasses, which might indicate the presence of phase separation.

The structural characteristics of bioactive glasses, i.e. their highly disrupted silicate network and the presence

of orthophosphate groups, are key to properties such as the ability to degrade, release ions, and form the biomimetic apatite surface layer described below. Unfortunately, they also cause bioactive glasses to have a pronounced tendency to crystallize when processed at higher temperatures, e.g. during the sintering of glass powders to make scaffolds or the drawing of fibers from the melt.

The crystallization tendency varies with glass composition, because more cross-linked silicate networks and lower concentrations of alkali ions (and higher concentrations of divalent ions) reduce it and improve glass processing. In many bioactive phosphosilicate glasses, crystalline silicate phases such as wollastonite (CaSiO₃) or sodium calcium silicates form during heat treatment [11]. Glasses with higher phosphate contents, by contrast, precipitate phosphate-containing crystal phases, including fluorapatite in fluoride-containing glasses [12]. In order to reduce the crystallization tendency of bioactive glasses and improve their processing, intermediate oxides such as magnesium oxide have been incorporated. The

combination of sodium and potassium oxide also improves processing by making use of the mixed alkali effect (Chapter 4.6).

The pronounced crystallization tendency of bioactive glasses such as Bioglass 45S5 is the reason why bioactive glass is available commercially in the form of granules (“morsels”) mostly rather than porous scaffolds and why the sol–gel route was investigated for the preparation of scaffolds as described in the following section. In recent years, however, new bioactive glasses, which are optimized for high-temperature processing without crystallization occurring (e.g. 13-93 or ICIE16; Table 1), have been developed and are being investigated for the preparation of scaffolds.

3 Bioactive Sol–Gel Glasses

The sol–gel process involves the room-temperature assembly of silica nanoparticles forming from the hydrolysis of alkoxide precursors, such as tetraethylorthosilicate (TEOS), the most popular precursor for silicate-based sol–gel glasses (Chapter 8.2). Under acidic catalysis, the nanoparticles agglomerate, polycondensation occurs through formation of —Si—O—Si— bonds, and the nanoparticles fuse together. When the condensation by-products are evaporated through drying, nanopores are left in the interstices between the nanoparticles. These nanopores are in the mesoporous (2–50 nm) range and are interconnected but random in their distribution.

Owing to the nature of the sol–gel process, the silicate network contains many Si—OH groups, which are a result of the polycondensation in a water-based sol. The protons (H^+ ions) act as network modifiers as do Na^+ ions in a melt-derived glass. This means that it is difficult to predict the network connectivity of the silicate network of a sol–gel glass from the nominal composition. After gelation the gel will contain a certain amount of H^+ , and, as drying and stabilization occurs, more Si—O—Si bonds form, increasing the connectivity. This transformation has an impact on degradation rate and bioactivity (see later).

In bioactive sol–gel glasses, phosphates are introduced as phosphate alkoxides (e.g. triethylphosphate [TEP]), whereas calcium is added to the sol as a salt, most commonly calcium nitrate. The phosphate plays a similar role here as it does in the melt-quenched glass structure, forming orthophosphate (PO_4^{3-}) groups. This is partly because TEP already has an orthophosphate-like structure before it is hydrolyzed [13]. Calcium incorporation is more challenging. When calcium nitrate was first used, the assumption was that when it dissolves in the sol, calcium will disrupt the formation of the silicate network,

taking its role as a network modifier. Actually, a silicate network forms at room temperature during the gelation stage, and the calcium only enters the network if the gel is heated above 450°C [14]. This has implications for the low-temperature synthesis of bioactive compositions, particularly for the preparation of hybrid materials combining organic and inorganic phases, as described in Section 8. Calcium alkoxides, e.g. calcium methoxyethoxide [15], can be selected in place of calcium nitrate, but their reaction rates are difficult to control so that their use is in its infancy [1, 8].

A benefit of the bottom-up sol–gel approach is that one can prepare porous scaffolds without having to sinter the glass (Figure 2) as a foaming step can be introduced prior to gelation. This foaming is achieved by vigorous agitation with the aid of a surfactant and hydrofluoric acid (HF) acting as a catalyst through formation of complexes with the silicate network, which increases the rate of gelation. This step is critical as the viscosity of the sol must increase rapidly to support the pores that form around the surfactant [1]. The surfactant in the sol–gel foaming process acts as a template for the formation of macropores, which are in excess of $500\ \mu\text{m}$. The surfactant is later removed by thermal processing.

An exciting potential application of sol–gel technology in biomedical research is the use of mesoporous silica nanoparticles in therapeutic applications. In these particles, the mesopores are in ordered arrays because surfactants have been used as templates. In this case, however, the surfactant molecules form micelles and pack as spheres into regular crystal-like arrays. When the surfactant is burned out, ordered arrays of interconnected mesopores remain. They are most useful in the form of nanoparticles, e.g. in the 50–150 nm range. Monodispersed nanoparticles can be synthesized through modification of the Stöber process. This process uses TEOS in water but employs a catalyst of high pH such as ammonium hydroxide, which not only promotes polycondensation but also causes the sol nanoparticles to repel each other, creating spherical nanoparticles.

These mesopores are useful because they can enhance the degradation rate of the silica (dense Stöber silica particles are nondegradable) and they can be used to carry drugs. An approach is to load the mesopores with a chemotherapy drug by diffusion in an appropriate medium. The hypothesis is that the particles can be injected into a tumor, or near it, and the tiny particles will pass through leaky blood vessel walls in the tumor, arriving at cancer cells. As the particles are small (e.g. 80 nm), they will enter the cells. The chemotherapy drug will diffuse out of the mesopores gradually, providing a sustained dose to the local area, which would be an advantage compared over biodegradable polymer capsules, which tend to release the drugs in a sudden burst. The challenge for the silica

Figure 2 Schematic of the sol-gel process and foaming step that can be introduced to produce highly porous scaffolds for bone regeneration.

particles is that the drug can leach out of the mesopores before the particle reaches the cancer cell. A recent study [16] reported the concept of a protocell that has mesoporous silica at its core, which contains the drug and quantum dots (Chapter 6.6) that will allow tracking of the device. Around the core is a polyethylene-glycol jacket that shields the particle from macrophage cells, which try to engulf it and remove it from circulation. Attached to the jacket are molecules that can target receptors specific to cancer cells and trigger the opening of the vesicles inside the intended targeted cells.

Bioactive versions of mesoporous particles are being investigated, but a challenge here is to get a high cation (e.g. calcium) content when salt precursors are used [17].

4 Degradation and Apatite Formation

When in contact with aqueous solutions (including body fluids *in vivo* as well as simulated physiological solutions such as simulated body fluid [SBF] or cell culture solutions during *in vitro* studies), water molecules can easily enter the silicate network. This is made possible owing to its highly disrupted structure with large numbers of non-bridging oxygens (large NBO/Si ratio; Table 1). This leads to rapid ion exchange whereby modifier cations are released into the surrounding medium and replaced by

protons from the solution, resulting in the formation of silanol (Si—OH) groups. Formation of this ion-depleted silicate (or silica gel) layer can be observed by Fourier transform infrared spectroscopy measurements. A main difference compared to more chemically stable silicate glasses is that in bioactive glasses this ion exchange process does not happen near the surface only, but results in ion release from deeper within the bulk of the glass. This difference has been highlighted in dynamic dissolution experiments in 2-amino-2-hydroxymethyl-propane-1,3-diol (Tris) buffer, which showed different release profiles (Figure 3) depending on whether the glass possessed high, intermediate, low, or no bioactivity [18]. Other factors, such as modifier-ion field strength, are also important and have a strong influence on solubility, with larger field strengths resulting in slower degradation.

When in contact with fluids, ions released from bioactive glasses – particularly calcium and phosphate – cause local supersaturation and subsequent precipitation of a surface layer of apatite (usually described as hydroxycarbonate apatite) (Figure 5). This layer is similar to the apatite found in mineralized human tissue including bone, dentine, and enamel, as it is nanocrystalline and shows various substitutions (e.g. with carbonate) in the crystal lattice. It has thus been described as biomimetic.

As a highly disrupted silicate network with a high concentrations of modifier cations facilitates water intrusion and ion exchange, variations in silicate network

Figure 3 Four typical initial ion release profiles for dynamic dissolution experiments of glasses: (a) 45S5, (b) 0106, (c) 1106, and (d) float glass in Tris buffer solution. Source: Reproduced from [18] with permission from Elsevier.

Figure 4 Time point of first apatite formation for $\text{Na}_2\text{O-CaO-SiO}_2$ silicate glasses immersed in simulated body fluid (as detected with thin-film X-ray diffractometry and Fourier transform infrared reflection spectroscopy) vs. network connectivity of the silicate network. Calculated and plotted based on data from [19].

polymerization and network connectivity result in slower or faster degradation and apatite formation (Figure 4). For glasses with increasing network connectivity, apatite formation is significantly delayed and, ultimately, not observed at all [19].

The rate of apatite formation is strongly affected by various other factors such as the presence of other ions (strontium or fluoride), presence of silanol groups (acting as nucleation sites), and a local pH rise (caused by the proton depletion of the aqueous medium as a result of exchange with modifier ions). Some bioactive glass components, such as magnesium or zinc, negatively affect apatite precipitation, as they are thought to inhibit apatite nucleation.

The *in vivo* degradation of bioactive glass is controlled by dissolution rather than by cellular or enzyme action [1]. The presence of silicon-containing species in urine has been observed in animal studies, suggesting that the dissolution products from bioactive glasses are excreted rather than accumulated in the body. This conclusion has been confirmed by clinical studies, which showed no elevated silicon concentrations in the blood of adults or children bearing bioactive glass implants.

Sol-gel glasses tend to undergo dissolution more rapidly than their melt-derived counterparts for two reasons. The first is that they have an enhanced specific surface area owing to their inherent nanoporosity. The second reason is that the sol-gel process leaves protons in the glass structure, acting as additional network modifiers, forming Si-OH groups, and reducing the network connectivity. These Si-OH groups on the glass surface

provide many sites for apatite nucleation. An additional benefit is that cells attach more readily to a nanotextured surface than to smooth surfaces. Melt-derived glasses, by contrast, tend to possess a nanorough surface after apatite formation only.

5 Biological Response

Bioglass® 45S5 positively affects the cell cycle, resulting in faster turnover of osteoblast (bone-forming) cells and, as a consequence, in a more mature cell population capable of producing mineralized tissue within a relatively short time [20]. Experiments using the dissolution products of 45S5 showed that osteoblast proliferation is increased via gene upregulation caused by ions released from the glass. This feature is particularly interesting for tissue engineering applications, as it suggests that supplementation with growth factors is not needed for bioactive glasses, unlike for other bioceramics such as calcium phosphates.

In vitro cell tests have shown an influence of the glass network connectivity on cell proliferation. More polymerized glasses show lower cell proliferation than less polymerized ones, in agreement with predictions based on *in vitro* immersion tests [21]. This effect can be explained by a range of factors such as slower apatite formation (reducing protein adsorption and initial cell attachment; Figure 5) and reduced ion release (in particular for calcium ions and silica species, which stimulate osteoblast proliferation and differentiation) for more polymerized glasses.

In vivo studies in rabbits have shown that Bioglass 45S5 particles lead to faster bone formation than synthetic hydroxyapatite particles and, unlike apatite, also completely degrade over time [22]. These results allow for bone regeneration, whereas glass particle dissolution correlates with bone formation. Further animal experiments in rabbits showed that bone formation is significantly reduced *in vivo* for glasses with increasing network connectivity (Figure 6). This confirmed the results from *in vitro* immersion tests showing much slower apatite formation with increasing network connectivity (Figure 4). Glasses with low network connectivity degraded *in vivo*, whereas those with a high network connectivity did not show signs of degradation but showed fibrous tissue encapsulation instead.

Vascularization is a critical step during tissue regeneration, as cell proliferation depends on the supply of oxygen and nutrients. Bioglass 45S5 has been suggested to enhance angiogenesis, i.e. the formation of new blood vessels *in vivo* [23].

6 Therapeutic Ions in Bioactive Glasses

One of the fundamental advantages of glasses is the possibility of varying their composition without many of the stoichiometric restraints imposed on crystals. It is therefore possible to incorporate cations, which have physiological activity and therapeutic properties, at varying concentrations. This would allow these ions to be released during the dissolution process. Particularly those ions acting as modifiers in the glass are released readily in exchange for protons from the surrounding aqueous medium (Chapter 5.11). Once released, these ions can

perform their therapeutic action [24], as demonstrated during *in vitro* experiments.

Calcium ions constitute one of the main components in many bioactive glasses and are readily released upon contact between glass and water. They favor not only apatite formation but also osteoblast differentiation. Strontium-substituted bioactive glasses stimulate the bone-forming cells (osteoblasts) while preventing osteoclasts from resorbing bone, as do strontium-containing drugs for treating osteoporosis [25]. This makes them particularly interesting implant materials for patients suffering from osteoporosis, as they could enhance bone regeneration without needing additional medication.

Cobalt-containing bioactive glasses enhanced angiogenesis *in vitro* by mimicking hypoxia, i.e. low oxygen pressure conditions.

Silver ions have long been known to exhibit antibacterial properties. Owing to a similar charge to size ratio as sodium ions, they can be incorporated into glasses by molten-salt ion exchange. The similarity between Ag^+ and Na^+ results in a similarly fast release of silver ions, allowing for antibacterial action. Zinc-containing bioactive glasses have been developed, as zinc ions are not only known to be bactericidal but also essential for wound healing. Appropriate release levels of zinc ions have to be maintained, however, as too high concentrations of zinc are cytotoxic.

Fluoride-containing bioactive glasses are of interest for dental applications to prevent dental caries, as fluoride-releasing bioactive glasses form fluorapatite in physiological solutions, which is more stable against acid attack than hydroxycarbonate apatite.

7 Applications of Bioglasses

Most commercial bioactive glass products (such as Peri-oGlas®, NovaBone®, NovaMin®, BonAlive, Biogran®, or Sylc®) are phosphosilicate glasses [26]. Other glasses used as biomaterials (e.g. phosphate or borate glasses) will only be mentioned briefly here.

7.1 Orthopedics

Bioglass 45S5 was originally developed as a bone-replacement material. Its first use was as middle-ear prostheses or for orbital-floor reconstruction [1]. In these early applications, monolithic devices were used, either custom-made for each individual patient or of standard (such as conical) shape. After animal studies had shown that bioactive glasses degrade while stimulating formation of new bone [27], interest grew in their use to regenerate bone. Implant studies in alveolar sockets showed that bioactive glass particles degrade over time, resorption rates being significantly faster than for demineralized freeze-dried bone allograft. The ability of Bioglass 45S5 to promote angiogenesis is of great advantage here, as bioactive glass implants can enhance vascularization and therefore accelerate bone regeneration.

Long-term studies on bioactive glass BonAlive S53P4 (Figure 7) have shown that the glass is well tolerated in children and adults, allowing for bone remodeling, vascularization, and cartilage repair. Depending on the size of the defect and nature or size of the glass granules used, the bioactive glass implant disappears gradually over periods of one to four years by a combination of surface reaction, dissolution processes, and possibly also resorption activity of osteoclast cells [29].

Bioactive glasses are particularly suitable for treating fractures and defects in cancellous (spongy) bone. Clinical results suggest that bioactive glass works as well as

Figure 7 Healing of infection and inflammation of bone marrow (*osteomyelitis*) in human tibia with bioactive glass S53P4. (a) Preoperative magnetic resonance image (MRI) showing osteomyelitis (inflammation) in tibia (white arrow). X-ray images showing this bone cavity filled with bioactive glass S53P4 (black arrow) (b) directly post-operation and (c) at six months' follow-up. Source: Reproduced from [28] with permission from Elsevier.

autograft, the gold-standard bone graft. Using bioactive glass for the treatment of fractures in cortical (compact) bone is more challenging. Here, repositioning and fixation of the fractured parts is usually necessary, making the procedure more complicated. As vascular supply in compact bone is usually not as good as in cancellous one, ion release from the glass and its surface reactions are slower, and glass degradation and bone regeneration take longer [29].

Another orthopedic application concerns spinal fusion, whereby two or more adjacent vertebrae are joined to immobilize vertebrae and prevent movement caused by instability in some medical conditions, which can cause severe pain. A challenging factor here is the need to grow bone between two neighboring vertebrae. Good fusion rates have been achieved with bioactive glasses [29], and computer tomography analyses suggest that fusion rates and bone formation are comparable to those obtained with autogenous bone implants.

Bioactive glass S53P4 possesses antibacterial properties *in vitro*, which constitutes a great benefit for the treatment of *osteomyelitis*, an inflammation of the bone, which often leads to bone destruction. Conventional treatment combines implants (e.g. poly(methyl methacrylate) [PMMA] beads) with local administration of antibiotics; however, relapses occur in many cases (more than 20% for patients suffering from chronic *osteomyelitis*) [29]. In a multicenter clinical study, bioactive glass S53P4 (Figure 7) was well tolerated by patients suffering from *osteomyelitis*; the patients recovered quickly and no relapses occurred in any of them.

In another promising approach, bioactive glass and organic polymers make up composite materials, which combine the unique properties of bioactive glasses, such as controlled ion release and bioactivity, with the flexibility and low stiffness of polymers. Current commercial products combine a lactic acid copolymer (L-lactide-co-D,L-lactide) with Bioglass 45S5 particles in composites, from which degradable screws are produced for fixing ligaments. By reinforcing polymers with bioactive glass fibers, the composite stiffness can be tailored to match the requirements of the implantation site, potentially including load-bearing sites [8]; however, such products are not yet used clinically.

7.2 Scaffolds

Bioactive glass scaffolds having an open, interconnected porous structure are of interest for use as bone fillers for the *in situ* regeneration of bone, as they allow for cell ingrowth while the bioactive glass degrades, releasing modifier ions with therapeutic benefits. Porous scaffolds are also being investigated for tissue engineering applications, where a scaffold is seeded with cells *ex situ* before

being implanted. Unfortunately porous scaffolds are yet to become clinical products, as bioactive glasses currently having approval for clinical use (Bioglass 45S5 and BonAlive S53P4) crystallize readily during the sintering process.

An ideal scaffold will stimulate the body's natural regenerative mechanisms, recruit cells such as bone marrow stem cells, stimulate them to form new bone, and enable the formation of blood vessels within the newly formed bone. Pore diameters and connections need to be large enough to allow cells, tissue, and blood vessels to penetrate the structure, and the scaffolds need to support cell attachment and proliferation and guide tissue growth. If the scaffold degrades over time, it will be replaced by newly formed, natural healthy bone [1].

The common way to prepare scaffolds is to form glass particles (powder, granules, or short fibers) into the desired architecture and sinter the particles together. Surgeons prefer scaffolds to look like cancellous (spongy) bone, and several approaches have been used to achieve such structures. Methods include gel-cast foaming (whereby a gel is formed by *in situ* polymerization of organic monomers and the gel, after binding to the glass particles, is foamed prior to gelation; Figure 8a), the foam-replica technique (whereby a polymer, e.g. polyurethane, foam is coated with a bioactive glass slurry and burned out following the sintering step) and sintering of glass powder together with a soluble material, e.g. sodium chloride, which is dissolved later and leaves pores behind [31]. These methods allow for variation of pore size, pore size distribution, or interconnectivity. Mimicking cancellous bone, however, is not necessarily the best approach, depending on the intended application. Methods such as unidirectional freezing of bioactive glass suspensions or rapid prototyping [32] have been used to create scaffolds with oriented microstructures and greatly improved mechanical strength (Figure 8b and c).

In order to maintain scaffold properties such as mechanical strength and bioactivity, crystallization needs to be controlled during sintering. Bioactive glass scaffolds often are actually glass-ceramics rather than amorphous glasses, as the bioactive glass used (usually Bioglass 45S5) partially or fully crystallizes during the sintering. As this greatly reduces bioactivity and mechanical strength, bioactive glasses with improved processing, i.e. with a lower crystallization tendency, such as compositions 13-93 and ICIE16 (Table 1) are preferable [1, 10].

7.3 Dentistry

Most glasses and glass-ceramics used in dentistry tend to be inert (Chapter 8.5), with the exception of compositions used in glass ionomer cements, which set by a neutralization reaction between an acid-degradable fluoroaluminosilicate glass and a solution of poly(acrylic acid). In

Figure 8 Scaffolds prepared from melt-derived bioactive glass by (a) gel-cast foaming (glass ICIE16) and (b, c) 3-D extrusion printing (glass 13-93). Source: (b, c) adapted from [30] with permission from Elsevier).

dentistry bioactive glasses are utilized either to treat bone defects or in oral care products (Section 7.4), but only a small number of commercial products are available. Bioactive glasses have also been implanted successfully in maxillofacial reconstruction surgery.

A large number of microorganisms are present in the oral cavity, where, together with other factors, they form a biofilm (the *plaque*) on the teeth. If not removed, this biofilm turns into *calculus* or *tartar*, a hardened dental plaque, leading to *gingivitis*, an inflammation of the gums. Gingivitis in advanced stages can give rise to *periodontitis*, an inflammatory disease affecting the tissue around teeth, where the gums recede from the teeth and the remaining pockets can become infected. If left untreated, this disorder can result in bone loss, loosening, and loss of teeth. Granules of Bioglass 45S5 (PerioGlas) have been used successfully to regenerate this bone and to promote new bone formation as well as the development of connective tissue in the periodontal area [29].

An early commercial application of bioactive glass in dentistry was filling extraction sockets to prevent the resorption of alveolar bone after tooth loss prior to placing a dental implant [8]. In early years, cones of Bioglass 45S5 were implanted into the alveolar sockets, whereas nowadays granular Bioglass is used instead to facilitate glass degradation and replacement by natural bone. Once the cavity has been filled and the jawbone regenerated, dental implants can be placed.

7.4 Oral Care

Fine bioactive glass (Bioglass 45S5) powder has recently been incorporated into commercial toothpastes for treating sensitive teeth. Dentine hypersensitivity is caused by dentinal tubules being exposed, thereby allowing external stimuli such as heat or cold to cause the sensation of pain.

Occlusion of these tubules has therefore long been recognized as the preferred treatment, which can be achieved by enhancing the natural process of apatite mineralization in the oral cavity. This is why most dentifrices treating dentine hypersensitivity contain ions, which aid in the precipitation of apatite, e.g. fluoride, strontium, phosphate, or calcium.

Bioactive glasses containing these ions also release them as soon as they are in contact with saliva in the mouth, causing supersaturation with regard to apatite. The original idea behind incorporating bioactive glass into toothpaste was that this would lead to apatite precipitation and the occlusion of dentinal tubules (Figure 9).

Recently, it has been recognized that toothpastes containing bioactive glass can also be used to remineralize enamel. In clinical trials a reduction in gingival bleeding, plaque growth, and an improved pain relief have been found when bioactive glass-containing toothpastes are used instead of control products. The success of these toothpastes has led to the development of new bioactive glass compositions, particularly fluoride-containing ones, which have been designed to stimulate the formation of fluoroapatite on the dentine, which is more resistant to acid attack than hydroxycarbonate apatite.

Other dental care applications of bioactive glass include the polishing of teeth by air-abrasion methods, a process that usually involves the use of particles such as sodium bicarbonate. According to patient reports, Bioglass 45S5 polishing results in a reduction in tooth sensitivity and also in whiter teeth than those treated with sodium bicarbonate [1].

7.5 Miscellaneous

Upon skin damage, in healthy individuals, a succession of different processes takes place to heal the wound. Within

Figure 9 Scanning electron microscope images of a dentine disc at seven days in Tris buffer solution with fluoride-containing glass powder showing dentinal tubules (white arrow) partially blocked by apatite crystals (black arrow). Inset shows exposed tubules in dentine disc after etching with citric acid before storage in Tris buffer.

just minutes of the damage, the first step is blood clotting (*hemostasis*). Particularly in patients suffering from diabetes, however, wound healing can be slowed down dramatically. Elevated blood sugar levels cause narrowing of the blood vessels, decrease the blood flow, and thus reduce the transport of oxygen and nutrients to the wound. This leads to slow- or non-healing wounds, which greatly lower the quality of life for the patients. Wound dressings made from bioactive borate glass nanofibers (Mirragen®) are an effective treatment of diabetic wounds [8], most likely by enabling the formation of blood clots. As the borate glass fibers degrade with time, the wound dressing pads do not require removal during follow-up care.

Glass spheres used for the *in situ* irradiation of malignant liver tumors have a composition differing very much from those of the bioactive glasses discussed. They are designed to be very stable in physiological fluids to prevent leakage of radioactive isotopes from the target organ. But, like bioactive glasses, they are introduced into the human body as part of a medical treatment. For this reason, they also need to be discussed here. In radiation therapy, malignant tumors are exposed to ionizing radiation, which damages DNA and therefore kills the cancerous tissue. One of several radioactive isotopes used to treat cancer is ^{90}Y , a beta emitter, which is produced *in situ* by neutron activation of the naturally occurring stable isotope ^{89}Y in microspheres made by flame spheroidization from yttrium aluminosilicate glass. In 2000 these microspheres (TheraSphere® [8]) obtained FDA

approval for the treatment of inoperable liver cancer. They are injected into the liver of the patients via the hepatic artery. They remain in the liver, emitting beta radiation *in situ*. As the radiation is delivered locally, much higher doses can be given than by external source without risk of damaging healthy tissue.

In more mundane applications, bioactive glasses are incorporated into a range of personal care products. Bio-glass 45S5 (under the trade name Vitryxx®) and some phosphate-free compositions are used in cosmetics (e.g. eye shadow or face powder), skin care, and even hair care products such as relaxers for hair straightening.

Finally, soluble phosphate glass boluses (Cosecure™) containing elements such as zinc, cobalt, or selenium are applied in veterinary medicine [33]. These boluses are placed inside the rumen of cattle or sheep, where they dissolve over a period of up to six months, providing the animals with trace elements and preventing deficiency.

8 Perspectives

Bioactive glasses are currently being investigated for many more applications; owing to long procedures necessary for acquiring approval for the use as medical devices, however, some of them may not be used clinically for another one or two decades. Nonetheless, some promising concepts will be introduced here.

In conventional composites, inorganic (bioactive glass) and organic (polymer) macroscopic phases are combined. Hybrid materials (Chapter 8.9), by contrast, have generated much interest in recent years as they combine the inorganic and organic phase at a molecular level, which makes the individual components indistinguishable above the micrometer scale and causes the hybrid to behave as a homogeneous material (Chapter 8.9). Their covalent bonding between co-networks of organic and inorganic molecules is needed to optimize their properties. For example, there is no risk of failure at the inorganic/organic interface, which is commonly encountered in conventional composites. Another great benefit of hybrids is that they can have “dial in” mechanical properties, from that of a stiff glass to an elastic polymer, to match those of either bone or cartilage [1]. A difficulty here is that the mechanical properties are not controlled by conventional parameters, such as polymer molecular weight, but rather by the way the molecules fit and bond together, which makes predicting the mechanical properties a challenge. For biomedical applications, a great benefit is that degradation rates can be controlled via the structure and that biodegradable hybrids, which are broken down in the body, for example, by enzymatic action, can be obtained if biodegradable polymers are used.

To make hybrids, polymers are introduced into the sol-gel process prior to gelation. No elevated temperatures are required, and therefore the polymers survive the processing, and the sol-to-gel transition can be exploited to allow foaming or 3-D printing of scaffolds. Much research remains to be done, however, as hybrid synthesis and processing involve many variables and advanced chemistry. The route to clinical products will be long as these are a completely new class of medical devices.

As their hardness, stiffness, and brittleness are much more similar to those of hard than soft tissue, bioactive glasses have so far been applied to bone and teeth mostly. In the last two decades, however, interest has grown in soft tissue applications [23] in the form of either fiber meshes (cf. wound healing as described in Section 7.5) or polymer matrix composites containing bioactive glass particles so that mechanical properties such as stiffness are more similar to those of soft tissue.

An area where the use of bioactive glass particles is promising is the investigation of incontinence resulting from urinary tract infections [23]. A form of clinical treatment includes the injection of suspensions of either collagen particles or inert particles prepared from polytetrafluoroethylene (PTFE) into the bladder neck, with the aim of increasing urethral resistance. In animal experiments with bioactive glass particle suspensions instead, urethral resistance does also increase without any inflammatory reactions, but an additional advantage is that, unlike inert particles, bioactive glass particles do not migrate within the body, but bond to the bladder soft tissue instead.

Phosphate glass tubes (4 mm in diameter and a few centimeters in length) have been investigated for nerve repair by bridging nerve defects [34]. When in contact with aqueous solutions, P_2O_5 - Na_2O - CaO -(MgO) phosphate glasses can dissolve completely, and one can vary their solubility by several orders of magnitude by changing the glass composition [8]. They also allow for the incorporation and subsequent release of therapeutically active ions, similar to phosphosilicate glasses (Section 6). But, unlike those of bioactive silicate glasses, many phosphate glass compositions do not show biomineralization, i.e. apatite formation, which is an advantage for soft tissue applications. Results from animal experiments in sheep suggest that nerve regeneration with degradable phosphate glass tubes is similarly effective as conventional forms of treatment.

Dental Glass-Ceramics

Wolfram Höland and Marcel Schweiger

Ivoclar Vivadent AG, R&D, Schaan, Principality of Liechtenstein

1 Introduction

The term dental glass-ceramics refers to biomaterials used to repair any defects in the natural tooth structure in order to restore the natural chewing function in a wider variety of situations and in a much nicer aesthetic way than with the traditional metal-based dental restoration [1, 2]. For vital teeth, restoration includes inlays, crowns, bridges, and veneers. Devitalized teeth are also built up with these biomaterials but require an appropriate dental post. Such a dental post may, for example, consist of a ZrO_2 rod that has to be adapted with a glass-ceramic [1]. The application and indication range of these materials differs quite significantly from that of *bioactive* materials [1]. The latter are designed to grow together with bone tissue to form a bond that does not involve any connective tissue. The *restorative* biomaterials, in contrast, have to be bonded to the natural (vital or devitalized teeth) with an adhesive.

The authors will refer to [1] for a history of the development of these materials. Here we will just state that in the 1900s inorganic dental restoratives initially involved porcelains and sintered ceramics on a feldspathic basis [3–5]. With the development and introduction of glass-ceramics in the 1950s, it was possible to control nucleation and crystallization of glasses and to design special properties. Therefore metal restorations were veneered with glass-ceramics, and metal-free restorations were possible. Glass-ceramics fulfill a high aesthetic solution for dental restoration to meet the patients need.

Irrespective of their application, be it of a technical or medical nature, dental glass-ceramics are produced

from a base glass. This glass must contain all the inorganic and chemical components necessary for controlled nucleation and crystallization processes [1]. Here, *in situ* mechanisms are the most convenient ones to use: the glass-ceramics develops from the base glass solely through its exposure to a time–temperature program. A wide variety of processes involving temperature and time relationships are available for this purpose, some of which involve multiple stage reactions. This chapter on dental glass-ceramics will show the usefulness of first producing a product in the form of a primary glass-ceramics, which is subsequently transformed into the finished product.

Because the most important criteria that have to be fulfilled in the development of restorative dental glass-ceramics are the needs of the patient, these will be addressed in detail in our first section. Subsequently, the properties of dental glass-ceramics will be discussed. Finally, a few groups of materials will be presented to illustrate the various ways in which glass-ceramics are used in dentistry currently and in a near future.
